AIEE Transactions Index for 1950

(Complete Index for Parts I and II of Volume 69)

1. Technical Subject Index

Accelerators, Ignitron Converters for High Energy Particle. Boyer, Marcum....1110–14
Accelerators, Ignitron Pulse Equipment for Particle. Herskind, Hudson....992–6
Accounting System, Fundamentals of the Automatic Telephone Message. Messar....255–68; disc. 269
Accuracy Counter-Type Tachometer, A New High-. Berry, Beattie....686–90; disc. 690
Accuracy Performance of the Selsyn Generator Control Transformer System, Static. Kronacher....645–54; disc. 653
Adjuster, Differential Relay Sensitivity. Headley....1203–05; disc. 1209
Air Circuit Breaker with 50,000 Ampere Interrupting Capacity at 600 Volts A-C, New Low-Voltage. Horn, Mikos....1654–7; disc. 1657
Air Circuit Breakers, An Air Delayed Selective Overcurrent Tripping Device for Low-Voltage. Tremblay, Horn....1649–53
Air Gaps, Dielectric Recovery Characteristics of Power Arcs in Large. McCann, Conner, Ellis....616–24; disc. 624
(Air Transportation) An Environment-Free 120-Volt D-C High Performance Limit Switch. Steelnagel....1280–93
(Air Transportation) Analogue Techniques for Turbojet Thrust Instrumentation. Van Valkenburg, Matthews....1342–6
(Air Transportation) Dynamic Characteristics of Carbon Pile Voltage Regulators. Mills....1347–52; disc. 1352
(Air Transportation) The Design of Reactors for Radio Interference Filters. Knudson....1294–8
Aircraft D-C Circuit Breakers for 28 and 120 Volts. Beall, Reifschneider....1283–8
Aircraft D-C System, Transient Analysis of a Voltage-Regulated. Scorgie....1318–23
Aircraft Electric Motors Need Test Equipment. Ross....1359–64
Aircraft Engine Failure at Take-off, Automatic Feathering—To Reduce the Hazard of. Kershaw....1328–34
Aircraft Inverter, An Amplistat Regulator Applied to a 5-Kva 400-Cycle. Morgan, Walley....1243–8; disc. 1248
Aircraft Manufacturer's Viewpoint, Aluminum Conductors from an. Schumacher....1335–41
Aircraft, Tracking Radio Noise on. Owen....1249–52
Aircraft, Wide Speed Range A-C Electric Systems for. James, Judkins, Mershon....1353–8; disc. 1358
Alco-GE 4,500-Horsepower Gas-Turbine Electric Locomotive, The. Morey....504–07
Allocation of the Capacity Benefits Resulting from Interconnecting Two or More Generating Systems, The Determination and. Watchorn....1180–6
A-C Components, The Extension of Amplistat Performance by. Morgan, Ogle, Wattenberger....986–91
A-C Electric Systems for Aircraft, Wide Speed Range. James, Judkins, Mershon....1353–8; disc. 1358
A-C Generators, Design Calculations for. Ginsberg....1274–80; disc. 1280
A-C Generators with Suddenly Applied Loads, Regulation of. Part II. Harder, Cheek, Clayton....395–405; disc. 405
(Part I—1944)
A-C Lead Networks for Servomechanisms, Improvements in the Characteristics of. McDonald....293–300
A-C Series Motors—A Design Method. Chang, Karr....1257–61; disc. 1261
A-C Servo Systems with Compensation for Carrier Frequency Changes, Phase Lead for. Notthoff....285–91; disc. 291
A-C Turbine Generators, Liquid Cooling of. Part II. Fechheimer....165–71; disc. 171
(Part I—1947)
Alternator, Variable Speed Drive Constant Frequency. Gould, Krupotich....745–7; disc. 747
Alternators, Symmetrical Short Circuits on Saturated. Mikhail....1554–62
Aluminum Conductors from an Aircraft Manufacturer's Viewpoint. Schumacher....1335–41
Aluminum Industry, The Theory of the Current Transductor and Its Application in the. Specht, Wagner....441–52; disc. 452
American Gas and Electric Company—Corona, Radio Influence, and Other Factors, Progress Report on Tidd 500-Kv Test Project of the. Sporn, Monteith....891–7; disc. 897
American Gas and Electric Company System, Selection, Design, and Operation of Power Transformers on. Lane, Gross, Pugh....786–93; disc. 793
Ampere Interrupting Capacity at 600 Volts A-C, New Low-Voltage Air Circuit Breaker with 50,000. Horn, Mikos....1654–7; disc. 1657
Amplidyne-Controlled Log Carriage Drive. Vincent....1124–9; disc. 1129
Amplifier Frequency Control, A Magnetic. Johnson, Schafer....613–15
Amplifiers, An Analysis of Transients and Feedback in Magnetic. Johnson, Latson....604–11; disc. 611
Amplifiers, An Analysis of Transients in Magnetic. VerPlanck, Finzi, Beaumariage....498–503
Amplifiers, Determination of Steady-State Performance of Self-Saturating Magnetic. Smith....1309–17
Amplifiers, General Characteristics of Magnetic. Finzi, Beaumariage....919–27
Amplifiers, Response Time of Magnetic. Harder, Horton....1130–8; disc. 1138
Amplistat Performance by A-C Components, The Extension of. Morgan, Ogle, Wattenberger....986–91
Amplistat Regulator Applied to a 5-Kva 400-Cycle Aircraft Inverter, An. Morgan, Walley....1243–8; disc. 1248
Anacom—Electric Analog, Computer, New Techniques on the. Harder, Carleton....547–56
Analog Computer, New Techniques on the Anacom—Electric. Harder, Carleton....547–56
Analogue Computer for Flight Simulation, A Generalized. Hall....308–20
Analogue Computer for Multicomponent Fractionation Calculations. Goels, Calvert....97–103
Analogue Computer Using the Photo Cell as a Nonlinear Element, An Electric. Koenig....1606–11
Analogue Techniques for Turbojet Thrust Instrumentation. Van Valkenburg, Matthews....1342–6
Analogue, Transients in Coupled Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-Ball. Magnuson....1525–30
Analogues in the Study of Transmission Line Vibration, Use of Techniques from Electrical. Lummis, Klopfenstein....1676–80
Analysis of a Voltage-Regulated Aircraft D-C System, Transient. Scorgie....1318–23
Analysis of Synchronous Machine Short Circuits. Camburn, Gross....671–8; disc. 678
Analysis of Transients and Feedback in Magnetic Amplifiers. Johnson, Latson....604–11; disc. 611
Analysis of Transients in Magnetic Amplifiers, An. VerPlanck, Finzi, Beaumariage....498–503
Analytical Study of Turbine Generator Rotor Ventilation, An Experimental and. Fechheimer....1563–9
Analyzed in Terms of a Rolling-Ball Analogue, Transients in Coupled Inductance-Capacitance Circuits. Magnuson....1525–30
Analyzer Solution of Complex Problems, Special Devices Aid Differential. Cook, Kirchmayer, Weygandt....1365–70; disc. 1370
Analyzing and Synthesizing Contactor Servomechanisms, A Frequency Response Method for. Kochenburger....270, 83; disc. 283
Apparatus Against Lightning, Evaluation of Lightning-Arrester Lead Length and Separation in Coordinated Protection of. Carpenter, Johnson, Saline....933–41; disc. 941
Apparatus, Quick and Accurate Production Testing on Large D-C. Baldwin, Barnhart....136–8
Application and Handling of Very Large Power Transformers on the System of the Bonneville Power Administration. Stevens....158–63; disc. 163
Application of Electronic Motor Drives to Printing Presses. Johnson, Stacey....816–19
Application of Power Transformers, Selection and. Seelye....830–3
Application of Transformer Differential Protection, Theory and. McKenna....1197–1202
Applications to Bonneville Power Administration System, Microwave. Stevens, Stringfield....1088–99
Arcs in Large Air Gaps, Dielectric Recovery Characteristics of Power. McCann, Conner, Ellis....616–24; disc. 624
Armature Circuit Inductance, Measurement and Calculation of D-C Machine. Snively, Robinson....1228–35; disc. 1235
Armature Windings, Current in Equalizer Connections of D-C Machine. Linville, Strang....1219–26; disc. 1226
Armatures, Solderless Commutator Joints for High Temperature Operation of Railway Traction. Reed....638–41
Arrester Location with Transformer Insulation Level, Co-ordination of Lightning. Winske, Bias....964–73; disc. 973
Arrester Protective Levels and Transformer Insulation, Margins Between Lightning. Vogel....110–12; disc. 112
Arrester Standard, New Lightning. Stewart, Defandorf....525–6
Arresters as a Criterion for Insulation Levels, Lightning. Rorden....84–91; disc. 91
Aspects of Community Dial Office Equipment, General. Burkett....1540–3
Aspects of Lightning Surges on Power Systems and Their Suppression, Some. Kaneff....1544–9
Audible Noise of Power Transformers. Gordy....45–50; disc. 50
Audio Noise in Transformers in Residential and Commercial Areas. Baugh....121–6; disc. 126
Audio Multiplexing Equipment with High Stability Carrier Supply, A Low Noise and Distortion. Beale....1028–37; disc. 1037
Audio Noise Investigation, Harmonic Index—A Tool for Transformer. Mutschler, Madden....115–18; disc. 118
Automatic Control of Ignitron Rectifier Stations. Cham, Derr....801–11; disc. 811
Automatic Control of Metal-Clad Switchgear Serving Oil Refinery Motors During Power System Disturbances. Horsfall, Thompson, Mills, Bobo....1600–03; disc. 1603
Automatic Feathering—To Reduce the Hazard of Aircraft Engine Failure at Take-off. Kershaw....1328–34
Automatic Telephone Message Accounting System, Fundamentals of the. Messar....255–68; disc. 269
Automatic Telephone Systems, The Universal Director in Strowger. Ostline....1080–7
Auxiliaries of the Consolidated Edison System, Thrust Bearing Problems and Their Solution on Turbine-Generator Units and. Driscoll, Otten....1642–7; disc. 1647
Auxiliary System, Bus Transfer Tests on 2,300-Volt Station. Johnson, Thompson....386–90; disc. 390

B

Ball Analogue, Transients in Coupled Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-. Magnuson....1525–30
Band Transformers for Linear Electronic Circuits, The Design of Broad-. Lord....1005–10
Bandwidth, The Direct Measurement of. Ammerman....27–31
Basic Design Considerations, Underground Conduit for Electric Power Systems—Fundamentals and. Watkins....1532–90; disc. 1590
Basic Impulse Insulation Levels for High-Voltage Systems, Proposed. Clem, Meador, Rudge, Powell....953–60; disc. 960
Basic Patterns for Arrangement of Electric Power Systems for Steel Mills. Finison....54–9; disc. 59
(Basic Sciences) Classification of the Reference Frames of a Synchronous Machine. Kron....720–7
(Basic Sciences) Steady-State Waves on Transmission Lines. Waidelich....1521–4
(Basic Sciences) The Calculation of the Capacitance of Coaxial Cylinders of Rectangular Cross-Section. Anderson....728–31
(Basic Sciences) Transients in Coupled Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-Ball Analogue. Magnuson....1525–30
(Basic Sciences) Transpositions and the Calculation of Inductance from Geometric Mean Distances. Boast....1531–4
Basic Theory Underlying Bell System Facilities Capacity Tables. Gracey....238–43; disc. 243
Bearing Problems and Their Solution on Turbine-Generator Units and Auxiliaries of the Consolidated Edison System, Thrust. Driscoll, Otten....1642–7; disc. 1647
Bell System Facilities Capacity Tables, Basic Theory Underlying. Gracey....238–43; disc. 243
Benefits Resulting from Interconnecting Two or More Generating Systems, The Determination and Allocation of the Capacity. Watchorn....1180–6

Beta Rays, Noncontacting Thickness Gauge Using. Clapp, Bernstein....488–90
Board for Steam-Electric Generating Plants, Centralized Control. Lowe, Hodgkins....1396–9; disc. 1399
Boiler-Turbine-Generator Units, Centralized Control Desirable for Single. Lind, Geiger....1176–9
Bonneville Power Administration, Applic a and Handling of Very Large Power Transformers on the System of the. Stevens....158–63; disc. 163
Bonneville Power Administration Relaying and Reclosing Program, The. Diemond, Wylie....1039–46; disc. 1046
Bonneville Power Administration System, Microwave Applications to. Stevens, Stringfield....1088–99
Boulder 287.5-Kv Transmission Lines, Thirteen-Year Lightning Performance of. Blakeslee, Kanouse....796–9; disc. 800
Brake Magnets, The Operating Speed of D-C. Ryan, Spitler....1253–7
Breaker, A New 69-Kv Oil-Blast Circuit. Rietz, Balentine....416–23; disc. 423
Breaker, Development and Testing of an Improved High-Voltage, High-Capacity Impulse Circuit. Rietz....15–25; disc. 25
Breaker with 50,000 Ampere Interrupting Capacity at 600 Volts A-C, New Low-Voltage Air Circuit. Horn, Mikos....1654–7; disc. 1657
Breakers, An Air Delayed Selective Overcurrent Tripping Device for Low-Voltage Air Circuit. Tremblay, Horn....1649–53
Breakers for 5,000,000- to 10,000,000-Kva Interrupting Capacity, High-Voltage Oil Circuit. Leeds, Friedrich....70–6; disc. 76
Breakers for 28 and 120 Volts, Aircraft D-C Circuit. Beall, Reifschneider....1283–8
Bridge, A Direct Reading High-Voltage Capacitance. Foley....692–8; disc. 698
Bridge, Resistance Wire Strain Gauges as Elements of the Wheatstone. Petrucelly....742–4
Bridge River Hydroelectric Development, The. Ingledow, Steede....845–54
Bridges, Power Factor Measurements on Polyphase and Multiconductor Cable Using Single-Phase. Greenfield....680–5; disc. 685
Broad-Band Transformers for Linear Electronic Circuits, The Design of. Lord....1005–10
Buck-Boost Voltage Regulator on Steady-State Power Limit, Effect of. Concordia....380–4; disc. 384
Buildings for Small Communities, Dial Telephone Central Office. Reese, Roys....1535–9
Bureau of Reclamation, Relaying Practices and Economical Switching Station Arrangements of the. Morgan, Worth....865–70; disc. 870
Burner Safety Devices, Flame Detectors for Domestic Fuel. Deubel....220–5
Bus Enclosures, Induced Currents in High-Capacity. Killian....1388–95; disc. 1395
Bus Transfer Tests on 2,300-Volt Station Auxiliary System. Johnson, Thompson....586–90; disc. 590
Bushing-Type Current Transformers, A New Line of Orthomagnetic. Farr....424–8
Bushing-Type Current Transformers for Metering Purposes, A Survey of. Camilli....429–40

C

Cable-Connected Equipment, Surge Protection of. Witzke, Bliss....527–38; disc. 539
Cable, Development of Improved Luminous Sign. Roehmann, Greenfield....350–5; disc. 355
Cable Ducts and Duct Assemblies, Heat Transfer Study on Power. Greebler, Barnett....357–64; disc. 364
Cable Manholes, Critical Inside Dimensions for Power. Halfmann....1576–80; disc. 1580
Cable Using Single-Phase Bridges, Power Factor Measurements on Polyphase and Multiconductor. Greenfield....680–5; disc. 685
Cables, A Two-Channel Carrier Telegraph System for Short Submarine. Newell, Cramer....61–5
Cables and a Surrounding Pipe or Duct Wall, The Thermal Resistance Between. Buller, Neher....342–7; disc. 347
Cables, Terminal Risers for Solid-Type Impregnated Paper. Del Mar....1592–7; disc. 1597
Calculation of D-C Machine Armature Circuit Inductance, Measurement and. Snively, Robinson....1228–35; disc. 1235
Calculation of Inductance from Geometric Mean Distances, Transpositions and the. Boast....1531–4
Calculation of the Capacitance of Coaxial Cylinders of Rectangular Cross-Section, The. Anderson....728–31
Calculations, Analogue Computer for Multicomponent Fractionation. Coels, Calvert....97–103
Calculations for A-C Generators, Design. Ginsberg....1274–80; disc. 1280
Calculations of Single-Phase Induction Motors, Suggested Improvements in the Performance. Thacker, Gopalakrishna....1–6; disc. 6
Calibrating Watt-Hour Meters, A New Device for. Robison, Wickham....732–4
Capacitance Bridge, A Direct Reading High-Voltage. Foley....692–8; disc. 698
Capacitance Circuits Analyzed in Terms of a Rolling-Ball Analogue, Transients in Coupled Inductance-. Magnusson....1525–30
Capacitance of Coaxial Cylinders of Rectangular Cross-Section, The Calculation of the. Anderson....728–31
Capacity at 600 Volts A-C, New Low-Voltage Air Circuit Breaker with 50,000 Ampere Interrupting. Horn, Mikos....1654–7; disc. 1657
Capacity Benefits Resulting from Interconnecting Two or More Generating Systems, The Determination and Allocation of the. Watchorn....1180–6
Capacitance Bus Enclosures, Induced Currents in High-. Killian....1388–95; disc. 1395
Capacity by the Probability Method, Determination of Reserve. Calabrese....1681–8; disc. 1688
Capacity, High-Voltage Oil Circuit Breakers for 5,000,000- to 10,000,000-Kva Interrupting. Leeds, Friedrich....70–6; disc. 76
Capacity Low-Voltage Power Fuse, A New High-Interrupting. Schuck....770–6; disc. 776
Carbon Pile Voltage Regulators, Dynamic Characteristics of. Mills....1347–52; disc. 1352
Carriage Drive, Amplidyne-Controlled Log. Vincent....1124–9; disc. 1129
Carrier Channel, Simulation Supervisory Control, Telemetering and Communication on Single-Frequency. Derr, Wren, Kresser....1115–21; disc. 1121
Carrier Current Test Equipment and Its Application, Modern. Brinton....777–80
Carrier Frequency Changes, Phase Lead for A-C Servo Systems with Compensation for. Northoff....285–91; disc. 291
Carrier Supply, A Low Noise and Distortion Audio Multiplexing Equipment with High Stability. Beale....1028–37; disc. 1037
Carrier System for Telephone Lines of Short or Medium Length, An Improved Transmitted. Brodie....1501–04
Carrier Telegraph System for Short Submarine Cables, A Two-Channel. Newell, Cramer....61–5
Carrier Telephone System, A Medium-Haul. Smith....1505–12
Carrier Telephone System, A Simplified 48-Channel. Erickson....1493–1500
Carrier-Type Servomechanism, Integral Controller for Use in. Cosgriff....1379–83
Cell as a Nonlinear Element, An Electric Analogue Computer Using the Photo. Koenig....1606–11
Central Control Rooms, Design and Operation of. Borgel....598–602; disc. 602
Central Office Buildings for Small Communities, Dial Telephone. Reese, Roys....1535–9
Centralized Control Board for Steam-Electric Generating Plants. Lowe, Hodgkins....1396–9; disc. 1399
Centralized Control Desirable for Single Boiler-Turbine-Generator Units. Lind, Geiger....1176–9
Centralized Instrumentation and Controls for Steam Electric Power Stations. Mallory....591–6; disc. 596
Changes, Investigation and Elimination of Unusual Vibration in the Field on a Large Single-Phase Frequency. Ballantyne, Allen, Baudry....1264–72; disc. 1272
Changes, Phase Lead for A-C Servo Systems with Compensation for Carrier Frequency. Northoff....285–91; disc. 291
Changes Produced by Single-Phase Loads, Effect of Three-Phase Motor Loads on Voltage. Fawcett, Fisher, Helm....1467–72
Channel Carrier Telegraph System for Short Submarine Cables, A Two-. Newell, Cramer....61–5
Channel Carrier Telephone System, A Simplified 48-. Erickson....1493–1590
Channel for Voice Communication, Relaying, Telemetering, and Supervisory Control, Field Testing a Microwave. Pattison, Reagan, Leyland, Gunter....945–51; disc. 951
Channel, Multistation Supervisory Control, Telemetering and Communication on Single-Frequency Carrier. Derr, Wren, Kresser....1115–21; disc. 1121
Characteristics of A-C Lead Networks for Servomechanisms, Improvements in the. McDonald....293–300
Characteristics of Carbon Pile Voltage Regulators, Dynamic. Mills....1347–52; disc. 1352
Characteristics of Magnetic Amplifiers, General. Finzi, Beaumariage....919–27
Characteristics of Power Arcs in Large Air Gaps, Dielectric Recovery. McCann, Conner, Ellis....616–24; disc. 624
Characteristics of Some Magnetic-Fluid Clutch Servomechanisms. Parziale, Tilton....150–7
(Chemical) Design and Control of Ferroalloy Furnaces. Andreae....557–62
(Chemical) Electric Equipment and Operation of Graphitizing Furnaces. Cole....563–6
(Chemical) Electrode Control and Associated Operating Mechanisms. Hauff....567–70; disc. 570
Circuit Breaker, A New 69-Kv Oil Blast. Rietz, Balentine....416–23; disc. 423
Circuit Breaker, Development and Testing of an Improved High-Voltage, High-Capacity Impulse. Rietz....15–25; disc. 25
Circuit Breaker with 50,000 Ampere Interrupting Capacity at 600 Volts A-C, New Low-Voltage Air. Horn, Mikos....1654–7; disc. 1657
Circuit Breakers, An Air Delayed Selective Overcurrent Tripping Device for Low-Voltage Air. Tremblay, Horn....1649–53
Circuit Breakers for 5,000,000 to 10,000,000-Kva Interrupting Capacity, High-Voltage Oil. Leeds, Friedrich....70–6; disc. 76
Circuit Breakers for 28 and 120 Volts, Aircraft D-C. Beall, Reifschneider....1283–8
Circuit Inductance, Measurement and Calculation of D-C Machine Armature. Snively, Robinson....1228–35; disc. 1235
Circuit Transformers, Control. Frank, Hauck....1376–8
Circuits, Analysis of Synchronous Machine Short. Camburn, Gross....671–8; disc. 678
Circuits Analyzed in Terms of a Rolling-Ball Analogue, Transients in Coupled Inductance-Capacitance. Magnusson....1525–30
Circuits Between Community Dial Offices, Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll. Brooke, Blackhall, Blashfield....1417–20
Circuits of the Shaded-Pole Motor with Space Harmonics, Equivalent. Kron....735–41
Circuits on Saturated Alternators, Symmetrical Short. Mikhail....1554–62
Circuits, The Design of Broad-Band Transformers for Linear Electronic. Lord....1005–10
Clampers in Video Transmission. Doba, Rieke....477–87
Class-H Material for the Insulation of Traction Motor Field Coils, A New-Resilient. Reed, Tyner....1158–61
Classification of the Reference Frames of a Synchronous Machine. Kron....720–7
Clutch Servomechanisms, Characteristics of Some Magnetic-Fluid. Parziale, Tilton....150–7
Coaxial Cylinders of Rectangular Cross-Section, The Calculation of the Capacitance of. Anderson....728–31
Coefficients for Hydrogen-Cooled Rotating Electric Machines, Surface Heat-Transfer. Snell, Norris, Buckland....174–85; disc. 185
Coefficients of Synchronous Machines and Their Application, Spring and Damping. Kilgore, Whitney....226–9; disc. 229
Coils, A New Resilient Class-H Material for the Insulation of Traction Motor Field. Reed, Tyner....1158–61
Combined Phase and Ground Distance Relaying. New....37–42; disc. 42
Commercial Areas, Audio Noise in Transformers in Residential and. Baugh....121–6; disc. 126
(Committee Report) A Method of Estimating Lightning Performance of Transmission Lines. (50-163)....1187–95; disc. 1195
(Committee Report) Maximum Short-Circuit Current of D-C Motors and Generators. (50-23)....146–9
(Committee Report) Protection of Electronic Power Converters. (50-133)....813–29
(Committee Report) Sensitive Ground Protection. (50-70)....473–5; disc. 475
Committees and Officers for 1950–51....1717–36
(Communication) A Frequency Response Method for Analyzing and Synthesizing Contactor Servomechanisms. Kochenburger....270–83; disc. 283
(Communication) A Medium-Haul Carrier Telephone System. Smith....1505–12
(Communication) A New Electronic Telegraph Regenerative Receiver. Ostendorf....32–6; disc. 36
(Communication) A Printing Telegraph Tape-to-Page Translator. Frost....79–83
(Communication) An Improved Transmitted Carrier System for Telephone Lines of Short or Medium Length. Brodie....1501–04
(Communication) Basic Theory Underlying Bell System Facilities Capacity Tables. Gracey....238–43; disc. 243
(Communication) Crossbar Tandem System. Collis....997–1004
(Communication) Dial Telephone Central Office Buildings for Small Communities. Reese, Roys....1535–9
(Communication) Fundamentals of the Automatic Telephone Message Accounting System. Meszar....255–68; disc. 269
(Communication) General Aspects of Community Dial Office Equipment. Burkett....1540–3
(Communication) Interexchange Tandem Trunking in the Los Angeles Metropolitan Area. Pfeiffer....1071–9
Communication on Single-Frequency Carrier Channel, Multistation Supervisory Control, Telemetering and. Derr, Wren, Kresser....1115–21; disc. 1121
Communication, Relaying, Telemetering, and Supervisory Control, Field Testing a Microwave Channel for Voice. Pattison, Reagan, Leyland, Gunter....945–51; disc. 951

(Communication) Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial Offices. Brooke, Blackhall, Blashfield 1417–20
(Communication) The Number 5 Crossbar Dial Telephone Switching System. Korn, Ferguson 244–54
(Communication) The Universal Director in Strowger Automatic Telephone Systems. Outline 1080–7
Communities, Dial Telephone Central Office Buildings for Small. Reese, Roys 1535–9
Community Dial Office Equipment, General Aspects of. Burkett 1540–3
Community Dial Offices, Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between. Brooke, Blackhall, Blashfield 1417–20
Commutation, Resistance. Olsen ..... 1207–15; disc. 1215
Complex Problems, Special Devices Aid Differential Analyzer Solution of. Cook, Kirchmayer, Weygandt ..... 1365–70; disc. 1370
Components, The Extension of Amplistat Performance by A-C. Morgan, Ogle, Wattenberger 986–91
Computer for Flight Simulation, A Generalized Analogue. Hall 308–20
Computer for Multicomponent Fractionation Calculations, Analogue. Geels, Calvert 97–105
Computer, New Techniques on the Anacom—Electric Analog. Harder, Carleton 547–56
Computer Using the Photo Cell as a Nonlinear Element, An Electric Analogue. Koenig 1606–11
(Computing Devices) An Electronic Simulator for Nonlinear Servomechanisms. Edwards, Johnson ..... 300–06; disc. 306
Commutator Joints for High Temperature Operation of Railway Traction Armatures, Solderless. Reed 638–41
Concepts of Thyratron Deionization Time, Statistical Nature and Physical. Romanowitz, Dow 368–79
Conditions, Ice Testing of Outdoor Disconnecting Switches to Simulate Field. Owens ..... 1488–91; disc. 1491
Conductors from an Aircraft Manufacturer's Viewpoint, Aluminum. Schumacher 1335–41
Conduit for Electric Power Systems—Fundamentals and Basic Design Considerations, Underground. Watkins ..... 1582–90; disc. 1590
Confinement, Transformer Noise and Its. McLean ..... 1409–15; disc. 1415
Connected Equipment, Surge Protection of Cable-Witzke, Bliss ..... 527–38; disc. 539
Connected Saturable Reactor with Control Source of Comparatively High Impedance, Series-. Storm 1299–1309
Connected Saturable Reactor with Control Source of Comparatively Low Impedance, Series. Storm 756–65
Connections for Phase Relays, A Study of Directional Element. Sonnemann ..... 1438–50; disc. 1450
Connections of D-C Machine Armature Windings, Current in Equalizer. Linville, Strang ..... 1219–26; disc. 1226
Conductors for Operation Above 230 Kv, Desert Measurements of Corona Loss on. Peterson, Cozzens, Carroll ..... 872–8; disc. 878
Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded Transmission Lines. Parks, Brownlee ..... 103–07; disc. 107
Considerations, Transformer Sound Level. Maslin ..... 1142–5; disc. 1145
Considerations, Underground Conduit for Electric Power Systems—Fundamentals and Basic Design. Watkins ..... 1582–90; disc. 1590
Consolidated Edison System, Thrust Bearing Problems and Their Solution on Turbine-Generator Units and Auxiliaries of the. Driscoll, Otten ..... 1642–7; disc. 1647
Constant Frequency Alternator, Variable Speed Drive. Gould, Krupotich ..... 745–7; disc. 747
Constant Using the Susceptance Variation Principle, An Improved Method of Measuring Dissipation Factor and Dielectric. Miller, Whelan 491–7
Contactor Servomechanisms, A Frequency Response Method for Analyzing and Synthesizing. Kochenburger ..... 270–83; disc. 283
Continuous Scavenging System for Hydrogen-Cooled Generators. Snell, Grobel 1625–36
Contributing Factors in Determining the Ratings of Power Transformers for Use on the Systems of the Hydro-Electric Power Commission of Ontario. Fleming, Lotimer ..... 1658–62; disc. 1662
Control, A Magnetic Amplifier Frequency. Johnson, Schafer 613–15
Control and Associated Operating Mechanisms, Electrode. Hanff ..... 567–70; disc. 570
Control Board for Steam-Electric Generating Plants, Centralized. Lowe, Hodgkins ..... 1396–9; disc. 1399
Control Circuit Transformers. Frank, Hauck 1376–8
Control Desirable for Single Boiler-Turbine-Generator Units, Centralized. Lind, Geiger 1176–9
Control for Tube Testing, High-Voltage Rectifier Equipment and. Durand 909–12
Control of Ferroalloy Furnaces, Design and. Andreae 557–62
Control of Gas Turbines for Power Generation. Hoffmann, Mellor, Starkey ..... 1637–41; disc. 1641
Control of Ignitron Rectifier Stations, Automatic. Cham, Derr ..... 801–11; disc. 811
Control of Large D-C Motors Supplied from Ignitron Rectifiers. Livingston 205–10
Control of Metal-Clad Switchgear Serving Oil Refinery Motors During Power System Disturbances, Automatic. Hornall, Thompson, Mills, Bobo ..... 1600–03; disc. 1603
Control Rooms, Design and Operation of Central. Borgel ..... 598–602; disc. 602
Control Source of Comparatively High Impedance, Series-Connected Saturable Reactor with. Storm 1299–1309
Control Source of Comparatively Low Impedance, Series-Connected Saturable Reactor with. Storm 756–65
Control System for a 4,500-Horsepower Gas-Turbine Electric Locomotive. Warrick 508–13
Control System Synthesis by Root Locus Method. Evans 66–9
Control, Telemetering and Communication on Single-Frequency Carrier Channel, Multistation Supervisory. Derr, Wren, Kresser ..... 1115–21; disc. 1121
Control Transformer System, Static Accuracy Performance of the Selsyn Generator. Kronacher ..... 645–53; disc. 653
Controlled Log Carriage Drive, Amplidyne-. Vincent ..... 1124–9; disc. 1129
Controller for Use in Carrier-Type Servomechanisms, Integral. Cosgriff 1379–83
Controls for Steam Electric Power Stations, Centralized Instrumentation and. Mallory ..... 591–6; disc. 596
Converters for High Energy Particle Accelerators, Ignitron. Boyer, Marcum 1110–14
Converters, Protection of Electronic Power. (Committee Report) 813–29
Cooled Generators at Elevated Gas Pressures, Loading of Hydrogen-. Snell ..... 186–99; disc. 199
Cooled Generators, Continuous Scavenging System for Hydrogen-. Snell, Grobel 1625–36
Cooled Rotating Electric Machines, Surface Heat-Transfer Coefficients for Hydrogen-. Snell, Norris, Buckland ..... 174–85; disc. 185
Cooling of A-C Turbine Generators, Liquid. Part II. Fechheimer ..... 165–71; disc. 171 (Part I–1947)
Co-ordination of Lightning Arrester Location with Transformer Insulation Level. Witzke, Bliss ..... 964–73; disc. 973
Cores, Single-Phase Power Transformer Formed. Gordy, Somerville 1384–7
Corona Loss on Conductors for Operation Above 230 Kv, Desert Measurements of. Peterson, Cozzens, Carroll ..... 872–8; disc. 878
Corona, Radio Influence, and Other Factors, Progress Report on Tidd 500-Kv Test Project of the American Gas and Electric Company— Sporn, Monteith ..... 891–7; disc. 897
Counter-Type Tachometer, A New High-Accuracy. Berry, Beattie ..... 686–90; disc. 690
Coupled Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-Ball Analogue, Transients in. Magnusson 1525–30
Critical Inside Dimensions for Power Cable Manholes. Halfmann ..... 1576–80; disc. 1580
Cross-Section, The Calculation of the Capacitance of Coaxial Cylinders of Rectangular. Anderson 728–31
Crossbar Dial Telephone Switching System, The Number 5. Korn, Ferguson 244–54
Crossbar Tandem System. Collis 997–1004
Current in Equalizer Connections of D-C Machine Armature Windings. Linville, Strang ..... 1219–26; disc. 1226
Current of D-C Motors and Generators, Maximum Short-Circuit. (Committee Report) 146–9
Current Test Equipment and Its Application, Modern Carrier. Brinton 777–80
Current Transductor and Its Application in the Aluminum Industry, The Theory of the. Specht, Wagner ..... 441–52; disc. 452
Current Transformers, A New Line of Orthomagnetic Bushing-Type. Farr 424–8
Current Transformers, A Primary Method of Measuring the Ratio and Phase Angle of. Brownlee 459–60
Current Transformers for Metering Purposes, A Survey of Bushing-Type. Camilli 429–40
Currents, Effect of Frequency on Perception. Daniel, Mansfield 1162–8
Currents in High-Capacity Bus Enclosures, Induced. Killian ..... 1388–95; disc. 1395
Customer's Premises, Protective Grounding of Electrical Installations on. Schirmer 657–9
Cylinders of Rectangular Cross-Section, The Calculation of the Capacitance of Coaxial. Anderson 728–31

D

Damping Coefficients of Synchronous Machines and Their Application, Spring and. Kilgore, Whitney ..... 226–9; disc. 229
Damping Torque at Low Speeds, Synchronous Machine. Concordia 1550–3
Deionization Time, Statistical Nature and Physical Concepts of Thyratron. Romanowitz, Dow 368–79
Delayed Selective Overcurrent Tripping Device for Low-Voltage Air Circuit Breakers, An Air. Tremblay, Horn 1649–53
Desert Measurements of Corona Loss on Conductors for Operation Above 230-Kv. Peterson, Cozzens, Carroll ..... 872–8; disc. 878
Design and Control of Ferroalloy Furnaces. Andreae 557–62
Design and Operation of Central Control Rooms. Borgel ..... 598–602; disc. 602
Design and Operation of Power Transformers on American Gas and Electric Company System, Selection. Lane, Gross, Pugh ..... 786–93; disc. 793
Design and Test on Electronic Exciter Supplied from Common Shaft-Driven Generator. Colsiaco, Johnson, Reilly ..... 328–35; disc. 335
Design as Applied to Polyphase Induction Motors, A Method of Total. Crouse 1434–7
Design Calculations for A-C Generators. Ginsberg ..... 1274–80; disc. 1280
Design Considerations, Underground Circuit for Electric Power Systems—Fundamentals and Basic. Watkins ..... 1582–90; disc. 1590
Design, Information Theory Applied to System. Tuller 1612–14
Design, Light Steel Tower Line. Osipovich ..... 1513–17; disc. 1517
Design Method, A-C Series Motors—A. Chang, Karr ..... 1257–61; disc. 1261
Design of a 3-Phase Transformer, Economical. Ciganek ..... 1371–4; disc. 1374
Design of Broad-Band Transformers for Linear Electronic Circuits, The. Lord 1005–10
Design of Log-Scale D-C Indicating Instruments, Principles of. Stimson, Taylor 101–15
Design of Reactors for Radio Interference Filters, The. Knudson 1294–8
Designers, Quiet Transformer Installations—A Problem for Both Equipment and Substation. Mendenhall, Taylor ..... 1148–52; disc. 1152
Detectors for Domestic Fuel Burner Safety Devices, Flame. Deubel 220–5
Determination and Allocation of the Capacity Benefits Resulting from Interconnecting Two or More Generating Systems, The. Watchorn 1180–6
Determination of Effective Oil Temperature in a Transformer. Beavers ..... 703–08; disc. 708
Determination of Reserve Capacity by the Probability Method. Calabrese ..... 1681–8; disc. 1688
Determination of Steady-State Performance of Self-Saturating Magnetic Amplifiers. Smith 1309–17
Development and Testing of an Improved High-Voltage, High-Capacity Impulse Circuit Breaker. Rietz ..... 15–23; disc. 25
Development of Fluid Mappers, The Further. Moore 1615–24
Development of Improved Luminous Sign Cable. Roehmann, Greenfield ..... 350–5; disc. 355
Development of Preferred Voltage Ratings for Transformers. St. Clair, Jalonack ..... 1049–59; disc. 1059
Development of the Standard for Neutral Grounding Devices. Clem 976–9
Development, The Bridge River Hydroelectric. Ingledow, Steede 845–54
Device for Calibrating Watt-Hour Meters, A New. Robison, Wickham 732–4
Device for Low-Voltage Air Circuit Breakers, An Air Delayed Selective Overcurrent Tripping. Tremblay, Horn 1649–53
Device for Metal-Clad Switchgear, A New Grounding and Testing. Krida, McCurry ..... 407–12; disc. 412
Devices Aid Differential Analyzer Solution of Complex Problems, Special. Cook, Kirchmayer, Weygandt ..... 1365–70; disc. 1370
Devices, Development of the Standard for Neutral Grounding. Clem 976–9
Devices, Flame Detectors for Domestic Fuel Burner Safety. Deubel 220–5
Dial Office Equipment, General Aspects of Community. Burkett 1540–3
Dial Telephone Central Office Buildings for Small Communities. Reese, Roys 1535–9
Dial Telephone Switching System, The Number 5 Crossbar. Korn, Ferguson 244–54
Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial Offices, Simplified Subscriber Toll. Brooke, Blackhall, Blashfield 1417–20
Dielectric Constant Using the Susceptance Variation Principle, An Improved Method of Measuring Dissipation Factor and. Miller, Whelan 491–7
Dielectric Recovery Characteristics of Power Arcs in Large Air Gaps. McCann, Conner, Ellis ..... 616–24; disc. 624

Differential Analyzer Solution of Complex Problems, Special Devices Aid. Cook, Kirchmayer, Weygandt.....1365–70; disc. 1370
Differential Protection, Theory and Application of Transformer. McKenna.....1197–1202
Differential Relay Sensitivity Adjuster. Headley.....1203–05; disc. 1205
Digital Recording and Telemetering. The Metrotype System of. Foster.....543–6; disc. 546
Dimensions for Power Cable Manholes, Critical Inside. Halfmann.....1576–80; disc. 1580
D-C Apparatus, Quick and Accurate Production Testing on Large. Baldwin, Barnhart.....136–8
D-C Brake Magnets, The Operating Speed of. Ryan, Spitler.....1253–7
D-C Circuit Breakers for 28 and 120 Volts, Aircraft. Beall, Reifschneider.....1283–8
Direct-Current Dynamos, Transient Response of. Koenig.....139–44; disc. 144
D-C High Performance Limit Switch, An Environment-Free 120-Volt. Stuelpnagel.....1289–93
D-C Indicating Instruments, Principles of Design of Log-Scale. Stimson, Taylor.....1011–15
D-C Machine Armature Circuit Inductance, Measurement and Calculation of. Snively, Robinson.....1228–35; disc. 1235
D-C Machine Armature Windings, Current in Equalizer Connections of. Linville, Strang.....1219–26; disc. 1226
D-C Motor Drives, Rectifier Equipment for Electronic. Mulhern, Crawford.....211–15
D-C Motors and Generators, Maximum Short-Circuit Current. (Committee Report).....146–9
D-C Motors Supplied from Ignitron Rectifiers, Control of Large. Livingston.....205–10
D-C System, Transient Analysis of a Voltage-Regulated Aircraft. Scorgie.....1318–23
Direct Measurement of Bandwidth, The. Ammerman.....27–31
Direct Reading High-Voltage Capacitance Bridge, A. Foley.....692–8; disc. 698
Directional Element Connections for Phase Relays, A Study of. Sonnemann.....1438–50; disc. 1450
Director in Stroger Automatic Telephone Systems, The Universal. Outline.....1080–7
Directors, Report of the Board of.....1690–1716
Disconnecting Switches to Simulate Field Conditions, Ice Testing of Outdoor. Owens.....1488–91; disc. 1491
Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An Improved Method of Measuring. Miller, Whelan.....491–7
Distance Power Transmission, Long-. Crary.....834–40; disc. 840
Distance Relaying, Combined Phase and Ground. New.....37–42; disc. 42
Distances, Transpositions and the Calculation of Inductance from Geometric Mean. Boast.....1531–4
Distortion Audio Multiplexing Equipment with High Stability Carrier Supply, A Low Noise and. Beale.....1028–37; disc. 1037
Disturbances, Automatic Control of Metal-Clad Switchgear Serving Oil Refinery Motors During Power System. Horsfall, Thompson, Mills, Bobo.....1600–03; disc. 1603
Domestic Fuel Burner Safety Devices, Flame Detectors for. Deutsch.....220–5
Drive, Amplidyne-Controlled Log Carriage. Vincent.....1124–9; disc. 1129
Drive Constant Frequency Alternator, Variable Speed. Gould, Krupotich.....745–7; disc. 747
Drives, Rectifier Equipment for Electronic D-C Motor. Mulhern, Crawford.....211–15
Drives to Printing Presses, Application of Electronic Motor. Johnson, Stacey.....216–19
Dry-Type Insulation for Instrument Transformers, A New. Pfuntner, Franck, D'Entremont.....453–8
Duct Wall, The Thermal Resistance Between Cables and a Surrounding Pipe or. Buller, Neher.....342–7; disc. 347
Ducts and Duct Assemblies, Heat Transfer Study on Power Cable. Greebler, Barnett.....357–64; disc. 364
Dynamic Characteristics of Carbon Pile Voltage Regulators. Mills.....1347–52; disc. 1352
Dynamos, Transient Response of Direct-Current. Koenig.....139–44; disc. 144

E

Economical Design of a 3-Phase Transformer. Ciganek.....1371–4; disc. 1374
Economical Switching Station Arrangements of the Bureau of Reclamation, Relaying Practices and. Morgan, World.....865–70; disc. 870
Effect of Buck-Boost Voltage Regulator on Steady-State Power Limits. Concordia.....380–4; disc. 384
Effect of Frequency on Perception Currents. Dalziel, Mansfield.....1162–8
Effect of Three-Phase Motor Loads on Voltage Changes Produced by Single-Phase Loads. Faucett, Fisher, Helm.....1467–72
Effects of Supply Line Unbalance on the Filtered Output Ripple of Polyphase Rectifiers. Hooper, McAdie.....766–70
Electric Analog Computer, New Techniques on the Anacom—. Harder, Carleton.....547–56
Electric Analogue Computer Using the Photo Cell as a Nonlinear Element, An. Koenig.....1606–11
Electric Equipment and Operation of Graphitizing Furnaces. Cole.....563–6
Electric Equipment for a Gas-Turbine Electric Locomotive, Rotating. Cohn.....514–18
Electric Equipment for Heavy-Media Separation Process. Bean, Blind.....1421–9
Electric Fences—Their Hazards, Types, Regulations, and Safe Application. Dalziel.....8–15
Electric Generating Plants, Centralized Control Board for Steam-. Lowe, Hodgkins.....1396–9; disc. 1399
Electric Locomotive, Control System for a 4,500-Horsepower Gas-Turbine. Warrick.....508–13
Electric Locomotive, The Alco-GE 4,500-Horsepower Gas-Turbine. Morey.....504–07
Electric Machines, Surface Heat-Transfer Coefficients for Hydrogen-Cooled Rotating. Snell, Norris, Buckland.....174–85; disc. 185
Electric Motors Need Test Equipment, Aircraft. Ross.....1359–64
Electric Power Stations, Centralized Instrumentation and Controls for Steam. Mallory.....591–6; disc. 596
Electric Power Systems for Steel Mills, Basic Patterns for Arrangement of. Finison.....54–9; disc. 59
Electric Power Systems—Fundamentals and Basic Design Considerations, Underground Conduit for. Watkins.....1582–90; disc. 1590
Electric Systems for Aircraft, Wide Speed Range A-C. James, Judkins, Mershon.....1353–8; disc. 1358
Electrical Analogues in the Study of Transmission Line Vibration, Use of Techniques from. Lemmis, Klopfenstein.....1676–80
Electrical Hazards to Farm Stock. Buchanan.....654–6
Electrical Installations on Customer's Premises, Protective Grounding of. Schirmer.....657–9
Electrical Instrumentation in Medical Research. Benjamin, Hale, Carstensen, Tompkins.....1324–7
Electrification, Rectifier-Type Motive Power for Railroad. Hibbard, Whittaker, Ames.....519–23; disc. 523
Electrode Control and Associated Operating Mechanisms. Hanff.....567–70; disc. 570
Electronic Circuits, The Design of Broad-Band Transformers for Linear. Lord.....1005–10
Electronic D-C Motor Drives, Rectifier Equipment for. Mulhern, Crawford.....211–15
Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods, Excitation Improvement—. Phillips, Lambert, Pattison.....338–40; disc. 340
Electronic Exciter Supplied from Common Shaft-Driven Generator, Design and Test on. Colaiaco, Johnson, Reilly.....328–35; disc. 335
Electronic Motor Drives to Printing Presses, Application of. Johnson, Stacey.....216–19
Electronic Power Converters, Protection of. (Committee Report).....813–29
Electronic Simulator for Nonlinear Servomechanisms, An. Edwards, Johnson.....300–06; disc. 306
Electronic Telegraph Regenerative Receiver, A New. Ostendorf.....32–6; disc. 36
(Electronics) A Magnetic Amplifier Frequency Control. Johnson, Schafer.....613–15
(Electronics) An Analysis of Transients and Feedback in Magnetic Amplifiers. Johnson, Latson.....604–11; disc. 611
(Electronics) An Analysis of Transients in Magnetic Amplifiers. VerPlanck, Finzi, Beaumariage.....498–503
(Electronics) Determination of Steady-State Performance of Self-Saturating Magnetic Amplifiers. Smith.....1309–17
(Electronics) General Characteristics of Magnetic Amplifiers. Finzi, Beaumariage.....919–27
(Electronics) High-Voltage Ignitron Rectifiers. Mulhern.....913–18
(Electronics) High-Voltage Rectifier Equipment and Control for Tube Testing. Durand.....909–12
(Electronics) Ignitron Converters for High Energy Particle Accelerators. Boyer, Marcum.....1110–14
(Electronics) Ignitron Pulse Equipment for Particle Accelerators. Herskind, Hudson.....992–6
(Electronics) Response Time of Magnetic Amplifiers. Harder, Horton.....1130–8; disc. 1138
(Electronics) Series-Connected Saturable Reactor with Control Source of Comparatively High Impedance. Storm.....1299–1309
(Electronics) Series Connected Saturable Reactor with Control Source of Comparatively Low Impedance. Storm.....756–65
(Electronics) Statistical Nature and Physical Concepts of Thyratron Deionization Time. Romanowitz, Dow.....368–79
(Electronics) The Direct Measurement of Bandwidth. Ammerman.....27–31
(Electronics) The Further Development of Fluid Mappers. Moore.....1615–24
Element, An Electric Analogue Computer Using the Photo Cell as a Nonlinear. Koenig.....1606–11
Element Connections for Phase Relays, A Study of Directional. Sonnemann.....1438–50; disc. 1450
Elements, Stability of Servomechanisms with Linearly Varying. Kirby.....1662–7; disc. 1667
Elimination of Unusual Vibration in the Field on a Large Single-Phase Frequency Changer, Investigation and. Ballantyne, Allen, Baudry.....1264–72; disc. 1272
Enclosures, Induced Currents in High-Capacity Bus. Killian.....1388–95; disc. 1395
Energized Systems, Measurement of Insulation Resistance on. Brancato, McClinton.....1238–42
Energy Particle Accelerators, Ignitron Converters for High. Boyer, Marcum.....1110–14
Engine Failure at Take-off, Automatic Feathering—To Reduce the Hazard of Aircraft. Kershaw.....1328–34
Environment-Free 120-Volt D-C High Performance Limit Switch, An. Stuelpnagel.....1289–93
Equalizer Connections of D-C Machine Armature Windings, Current in. Linville, Strang.....1219–26; disc. 1226
Equipment, Aircraft Electric Motors Need Test. Ross.....1359–64
Equipment and Control for Tube Testing, High-Voltage Rectifier. Durand.....909–12
Equipment and Its Application, Modern Carrier Current Test. Brinton.....777–80
Equipment and Operation of Graphitizing Furnaces, Electric. Cole.....563–6
Equipment and Substation Designers, Quiet Transformer Installations—A Problem for Both. Mendenhall, Taylor.....1148–52; disc. 1152
Equipment for a Gas-Turbine Electric Locomotive, Rotating Electric. Cohn.....514–18
Equipment for Electronic D-C Motor Drives, Rectifier. Mulhern, Crawford.....211–15
Equipment for Heavy-Media Separation Process, Electric. Bean, Blind.....1421–9
Equipment for Particle Accelerators, Ignitron Pulse. Herskind, Hudson.....992–6
Equipment General Aspects of Community Dial Office. Burkett.....1540–3
Equipment, Surge Protection of Cable-Connected. Wrake, Bliss.....527–38; disc. 539
Equipment with High Stability Carrier Supply, A Low Noise and Distortion Audio Multiplexing. Beale.....1028–37; disc. 1037
Equivalent Circuits of the Shaded-Pole Motor With Space Harmonics. Kron.....735–41
Evaluation of Lightning-Arrester Lead Length and Separation in Co-ordinated Protection of Apparatus Against Lightning. Carpenter, Johnson, Saline.....933–41; disc. 941
Excitation Experience at Grand Coulee, Hydroelectric Generator. Killgore, Holmdahl.....855–60
Excitation Improvement—Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods. Phillips, Lambert, Pattison.....338–40; disc. 340
Excitation System Performance with Motor-Driven Exciters. Mellor, Temoshok.....321–7
Exciter Supplied from Common Shaft-Driven Generator, Design and Test on Electronic. Colaiaco, Johnson, Reilly.....328–35; disc. 335
Exciters, Excitation System Performance with Motor-Driven. Mellor, Temoshok.....321–7
Expansion of the System of the Southern California Edison Company. Kroneberg.....861–4
Experience at Grand Coulee, Hydroelectric Generator Excitation. Killgore, Holmdahl.....855–60
Experiences with Resonant Grounding in a Large 34.5-Kv System, Practical. Brown, Gross.....1401–06; disc. 1406
Experimental and Analytical Study of Turbine Generator Rotor Ventilation, An. Fechheimer.....1563–9
Extension of Amplitat Performance by A-C Components, The. Morgan, Ogle, Wattenberger.....986–91

F

Facilities Capacity Tables, Basic Theory Underlying Bell System. Gracey.....238–43; disc. 243
Factor and Dielectric Constant Using the Susceptance Variation Principle, An Improved Method of Measuring Dissipation. Miller, Whelan.....491–7
Factor Measurements on Polyphase and Multiconductor Cable Using Single-Phase Bridges, Power. Greenfield.....680–5; disc. 685
Factors in Determining the Ratings of Power Transformers for Use on the Systems of the Hydro-Electric Power Commission of Ontario, Contributing. Fleming, Lotimer.....1658–62; disc. 1662
Failure at Take-off, Automatic Feathering—To Reduce the Hazard of Aircraft Engine. Kershaw.....1328–34
Failures of Rubber Insulation Caused by Soil Microorganisms. Blake, Kitchin, Pratt.....748–54; disc. 754

Farm Stock, Electrical Hazards to. Buchanan....654–6
Fatigue Life of Steel Strand, Vibration and. Little, MacMillan, Majercak.....1473–8; disc. 1478
Feathering—To Reduce the Hazard of Aircraft Engine Failure at Take-off, Automatic. Kershaw...1328–34
Feedback in Magnetic Amplifiers, An Analysis of Transients and. Johnson, Latson.....604–11; disc. 611
Fences—Their Hazards, Types, Regulations, and Safe Application, Electric. Dalziel.....8–15
Ferroalloy Furnaces, Design and Control of. Andreae 557–62
Field Coils, A New Resilient Class-H Material for the Insulation of Traction Motor. Reed, Tyner.....1158–61
Field Conditions, Ice Testing of Outdoor Disconnecting Switches to Simulate. Owens..1488–91; disc. 1491
Field Testing a Microwave Channel for Voice Communication, Relaying, Telemetering, and Supervisory Control. Pattison, Reagan, Leyland, Gunter.....G945–51; disc. 951
Filter Output Ripple of Polyphase Rectifiers, Effects of Supply Line Unbalance on the. Hooper, McAdie 766–70
Filters, The Design of Reactors for Radio Interference. Knudson.....1294–8
5,000-Kva Underground Substation, A. Sinnott. .....882–9; disc. 889
Flame Detectors for Domestic Fuel Burner Safety Devices. Deubel.....220–5
Flight Simulation, A Generalized Analogue Computer for. Hall.....308–20
Fluid Clutch Servomechanisms, Characteristics of Some Magnetic-. Parziale, Tilton.....150–7
Fluid Mappers, The Further Development of. Moore 1615–24
Flux Induction Heating, Transverse. Baker.....711–19
Formed Cores, Single-Phase Power Transformer. Gordy, Somerville.....1384–7
Fractionation Calculations, Analogue Computer for Multicomponent. Goetz, Calvert.....97–103
Frames of a Synchronous Machine, Classification of the Reference. Kron.....720–7
Frequencies, Indicating Instruments at the Servomechanism. Pritchett, Saunders.....980–5
Frequency Alternator, Variable Speed Drive Constant. Gould, Krupovich.....745–7; disc. 747
Frequency Carrier Channel, Multistation Supervisory Control, Telemetering, and Communication on Single-. Derr, Wren, Kreuzer..1115–21; disc. 1121
Frequency Changer, Investigation and Elimination of Unusual Vibration in the Field on a Large Single-Phase. Ballantyne, Allen, Baudry.....1264–72; disc. 1272
Frequency Changes, Phase Lead for A-C Servo Systems with Compensation for Carrier. Notthoff.....285–91; disc. 291
Frequency Control, A Magnetic Amplifier. Johnson, Schafer.....613–15
Frequency on Perception Currents, Effect of. Dalziel, Mansfield.....1162–8
Frequency Response Method for Analyzing and Synthesizing Contactor Servomechanisms, A. Kochenburger.....270–83; disc. 283
Fuel Burner Safety Devices, Flame Detectors for Domestic. Deubel.....220–5
Fundamentals and Basic Design Considerations, Underground Conduit for Electric Power Systems—. Watkins.....1582–90; disc. 1590
Fundamentals of the Automatic Telephone Message Accounting System. Mestar....255–68; disc. 269
Furnaces, Design and Control of Ferroalloy. Andreae 557–62
Furnaces, Electric Equipment and Operation of Graphitizing. Cole.....563–6
Fuse, A New High-Interrupting Capacity Low-Voltage Power. Schuck.....770–6; disc. 776

Gaps, Dielectric-Recovery Characteristics of Power Arcs. McCann, Conner, Ellis.....616–24; disc. 624
Gaps for Voltage Measurement, The Irradiation of Spark. Hardy, Craggs.....584–90
Gas Pressures, Loading of Hydrogen-Cooled Generators at Elevated. Snell.....186–99; disc. 199
Gas-Turbine Electric Locomotive, Control System for a 4,500-Horsepower. Warrick.....508–13
Gas-Turbine Electric Locomotive, Rotating Electric Equipment for a. Coho.....514–18
Gas-Turbine Electric Locomotive, The Alco-GE 4,500-Horsepower. Morey.....504–07
Gas Turbines for Power Generation, Control of. Hoffmann, Mellor, Starkey.....1637–41; disc. 1641
Gauge Using Beta Rays, Noncontacting Thickness. Clapp, Bernstein.....488–90
Gauges as Elements of the Wheatstone Bridge, Resistance Wire Strain. Petrucelly.....742–4
General Aspects of Community Dial Office Equipment. Burkett.....1540–3
General Characteristics of Magnetic Amplifiers. First, Beaumariage.....919–27
GE 4,500-Horsepower Gas-Turbine Electric Locomotive, The Alco-. Morey.....504–07
Generalized Analogue Computer for Flight Simulation, A. Hall.....308–20
Generating Plants, Centralized Control Board for Steam-Electric. Lowe, Hodgkins.....1396–9; disc. 1399
Generating Stations, The Choice of Main Power Transformers for. Dillow, Butler.....781–5; disc. 785
Generating Systems, The Determination and Allocation of the Capacity Benefits Resulting from Interconnecting Two or More. Watchorn.....1180–6
Generation, Control of Gas Turbines for Power. Hoffmann, Mellor, Starkey.....1637–41; disc. 1641
Generator Control Transformer System, Static Accuracy Performance of the Selsyn. Kronacher.....645–53; disc. 653
Generator, Design and Test on Electronic Exciter Supplied from Common Shaft-Driven. Colaiaco, Johnson, Reilly.....328–35; disc. 335
Generator Excitation Experience at Grand Coulee, Hydroelectric. Killgore, Holmdahl.....855–60
Generator Rating of Induction Motors. Smith..129–35
Generator Rotor Ventilation, An Experimental and Analytical Study of Turbine. Fechheimer..1563–9
Generator Units and Auxiliaries of the Consolidated Edison System, Thrust Bearing Problems and Their Solution on Turbine-. Driscoll, Otten.....1642–7; disc. 1647
Generator Units, Centralized Control Desirable for Single Boiler Turbine. Lind, Geiger.....1176–9
Generators as Compared to Conventional Methods, Excitation Improvement—Electronic Excitation and Regulation of Electric. Phillips, Lambert, Pattison .....338–40; disc. 340
Generators at Elevated Gas Pressures, Loading of Hydrogen-Cooled. Snell.....186–99; disc. 199
Generators, Continuous Scavenging System for Hydrogen-Cooled. Snell, Grobel.....1625–36
Generators, Design Calculations for A-C. Ginsberg .....1274–80; disc. 1280
Generators, Liquid Cooling of A-C Turbine. Part II. Fechheimer.....165–71; disc. 171 (Part I–1947)
Generators, Maximum Short-Circuit Current of D-C Motors and. (Committee Report).....146–9
Generators with Suddenly Applied Loads, Regulation of A-C. Part II. Harder, Cheek, Clayton.....395–405; disc. 405 (Part I–1944)
Geometric Mean Distances, Transpositions and the Calculation of Inductance from. Boast.....1531–4
Georges Phenomenon—Induction Motors with Unbalanced Rotor Impedances, The. Garbarino, Gross.....1569–74; disc. 1574
Gradient Meter, A Voltage. Tremaine, Cheek.....633–7; disc. 637
Grand Coulee, Hydroelectric Generator Excitation Experience at. Killgore, Holmdahl.....855–60
Graphitizing Furnaces, Electric Equipment and Operation of. Cole.....563–6
Ground Distance Relaying, Combined Phase and. New .....37–42; disc. 42
Ground Protection, Sensitive. (Committee Report) .....473–5; disc. 475
Grounding and Testing Device for Metal-Clad Switchgear, A New. Krida, McCurry..407–12; disc. 412
Grounding Devices, Development of the Standard for Neutral. Clem.....976–9
Grounding in a Large 34.5-Kv System, Practical Experiences with Resonant. Brown, Gross.....1401–06; disc. 1406
Grounding of Electrical Installations on Customer's Premises, Protective. Schirmer.....657–9

H

Harmonic Index—A Tool for Transformer Audio Noise Investigation. Mutschler, Madden.....115–18; disc. 118
Harmonics, Equivalent Circuits of the Shaded-Pole Motor with Space. Kron.....735–41
Haul Carrier Telephone System, A Medium-. Smith 1505–12
Hazard of Aircraft Engine Failure at Take-off, Automatic Feathering—To Reduce the. Kershaw.....1328–34
Hazards to Farm Stock, Electrical. Buchanan....654–6
Hazards, Types, Regulations, and Safe Application, Electric Fences—. Dalziel.....8–15
Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric Machines, Surface. Snell, Norris, Buckland.....174–85; disc. 185
Heat Transfer Study on Power Cable Ducts and Duct Assemblies. Grezebler, Barnett..357–64; disc. 364
Heating, Transverse Flux Induction. Baker.....711–19
Heavy-Media Separation Process, Electric Equipment for. Bean, Blind.....1421–9
High-Accuracy Counter-Type Tachometer, A New. Berry, Beattie.....686–90; disc. 690
High-Capacity Bus Enclosures, Induced Currents in. Killian.....1368–95; disc. 1395
High Interrupting Capacity Low-Voltage Power Fuse, A New. Schuck.....770–6; disc. 776
High-Speed Reclosing on Long and Heavily Loaded Transmission Lines, Consideration of Requirements and Limitations of Relaying and. Parks, Brownlee .....103–07; disc. 107
High Voltage Capacitance Bridge, A Direct Reading. Foley.....692–8; disc. 698
High-Voltage, High-Capacity Impulse Circuit Breaker, Development and Testing of an Improved. Riers .....15–25; disc. 25
High-Voltage Ignitron Rectifiers. Mulhern.....913–18
High-Voltage Oil Circuit Breakers for 3,000,000 to 10,000,000-Kva Interrupting Capacity. Leeds, Friedrich.....70–6; disc. 76
High-Voltage Rectifier Equipment and Control for Tube Testing. Durand.....909–12
High-Voltage Systems, Proposed Basic Impulse Insulation Levels for. Clem, Meador, Rudge, Powell .....953–60; disc. 960
High-Voltage Transmission Lines, Relay Protection for Medium Length. Kinghorn.....461–5; disc. 465
Hook-On Method, Power Measurement by the. Corson, Nylander.....699–702
Horn-Gap Switches, Interrupting Ability of. Andrews, Janes, Anderson.....1016–24; disc. 1025
Horsepower Gas-Turbine Electric Locomotive, Control System for a 4,500-. Warrick.....508–13
Horsepower Gas-Turbine Electric Locomotive, The Alco-GE 4,500-. Morey.....504–07
Hydroelectric Development, The Bridge River. Ingledow, Steede.....845–54
Hydroelectric Generator Excitation Experience at Grand Coulee. Killgore, Holmdahl.....855–60
Hydroelectric Power Commission of Ontario, Contributing Factors in Determining the Ratings of Power Transformers for Use on the Systems of the. Fleming, Lotimer.....1658–62; disc. 1662
Hydroelectric Power Plants, Underground. Gaiger.....1169–75
Hydroelectric Power Stations in Sweden, Underground. Rusck, Westerberg.....928–32
Hydrogen-Cooled Generators at Elevated Gas Pressures, Loading of. Snell.....186–99; disc. 199
Hydrogen-Cooled Generators, Continuous Scavenging System for. Snell, Grobel.....1625–36
Hydrogen-Cooled Rotating Electric Machines, Surface Heat-Transfer Coefficients for. Snell, Norris, Buckland.....174–85; disc. 185

I

Ice Testing of Outdoor Disconnecting Switches to Simulate Field Conditions. Owens.....1488–91; disc. 1491
Ignitron Converters for High Energy Particle Accelerators. Boyer, Marcum.....1110–14
Ignitron Pulse Equipment for Particle Accelerators. Herskind, Hudson.....992–6
Ignitron Rectifier Stations, Automatic Control of. Cham, Derr.....801–11; disc. 811
Ignitron Rectifiers, Control of Large D-C Motors Supplied From. Livingston.....205–10
Ignitron Rectifiers, High-Voltage. Mulhern....913–18
Impedance Repeater, A Negative. Merrill.....1461–6
Impedance, Series-Connected Saturable Reactor with Control Source of Comparatively High. Storm 1899–1309
Impedance, Series-Connected Saturable Reactor with Control Source of Comparatively Low. Storm.....756–65
Impedances, The Georges Phenomenon—Induction Motors with Unbalanced Rotor. Garbarino, Gross.....1569–74; disc. 1574
Impregnated Paper Cables, Terminal Risers for Solid-Type. Del Mar.....1593–7; disc. 1597
Improved Luminous Sign Cable, Development of. Roehmann, Greenfield.....350–5; disc. 355
Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An. Miller, Whelan.....491–7
Improved Reclosing Relay, An. Goff.....1480–4; disc. 1484
Improved Transmitted Carrier System for Telephone Lines of Short or Medium Length, An. Brodie 1501–04
Improvement—Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods, Excitation. Phillips, Lambert, Pattison .....338–40; disc. 340
Improvements in the Characteristics of A-C Lead Networks for Servomechanisms. McDonald..293–300
Improvements in the Performance Calculations of Single-Phase Induction Motors, Suggested. Thacker, Gopalakrishna.....1–6; disc. 6
Impulse Circuit Breaker, Development and Testing of an Improved High-Voltage, High-Capacity. Riers .....15–25; disc. 25

Impulse Insulation Levels for High-Voltage Systems, Proposed Basic. Clem, Meador, Rudge, Powell ....953–60; disc. 960
Impulse Measurements by Repeated-Structure Networks. Dawes, Thomas, Drought....571–80; disc. 580
Incremental Losses in Power Transmission Networks, Total and. Ward, Eaton, Hale...626–31; disc. 631
Index—A Tool for Transformer Audio Noise Investigation, Harmonic. Mutschler, Madden....115–18; disc. 118
Indicating Instruments at the Servomechanisms Frequencies. Pritchett, Saunders....980–5
Indicating Instruments, Principles of Design of Log-Scale. Stimson, Taylor....1011–15
Induced Currents in High-Capacity Bus Enclosures. Killian....1388–95; disc. 1395
Inductance-Capacitance Circuits Analyzed in Terms of a Rolling-Ball Analogue, Transients in Coupled. Magnusson....1525–30
Inductance from Geometric Mean Distances, Transpositions and the Calculation of. Boast....1531–4
Inductance, Measurement and Calculation of D-C Machine Armature Circuit. Snively, Robinson ....1228–35; disc. 1235
Inductances of Synchronous Machines, Per-Unit. Kirschbaum....231–8
Induction Heating, Transverse Flux. Baker....711–19
Induction Motors, A Method of Total Design as Applied to Polyphase. Crouse....1434–7
Induction Motors, Generator Rating of. Smith....129–35
Induction Motors, Suggested Improvements in the Performance Calculations of Single-Phase. Thacker, Gopalakrishna....1–6; disc. 6
Induction Motors with Unbalanced Rotor Impedances, The Georges Phenomenon—. Garbarino, Gross ....1569–74; disc. 1574
(Industrial) Basic Patterns for Arrangement of Electric Power Systems for Steel Mills. Finison....54–9; disc. 59
Industry, The Theory of the Current Transductor and Its Application in the Aluminum. Specht, Wagner ....441–52; disc. 452
Information Theory Applied to System Design. Tuller 1612–14
Inside Dimensions for Power Cable Manholes, Critical. Halfmann....1576–80; disc. 1580
Installations—A Problem for Both Equipment and Substation Designers, Quiet Transformer. Mendenhall, Taylor....1148–52; disc. 1152
Installations on Customer's Premises, Protective Grounding of Electrical. Schirmer....657–9
Instrument Transformers, A New Dry-Type Insulation for. Pfuntner, Franck, D'Entremont....453–8
Instrumentation, Analogue Techniques for Turbojet Thrust. Van Valkenburg, Matthews....1342–6
Instrumentation and Controls for Steam Electric Power Stations, Centralized. Mallory...591–6; disc. 596
Instrumentation in Medical Research, Electrical. Benjamin, Hale, Carstensen, Tompkins....1324–7
(Instruments) A Direct Reading High-Voltage Capacitance Bridge. Foley....692–8; disc. 698
(Instruments) A New High-Accuracy Counter-Type Tachometer. Berry, Beattie....686–90; disc. 690
(Instruments) A Voltage Gradient Meter. Tremaine, Cheek....633–7; disc. 637
Instruments at the Servomechanism Frequencies, Indicating. Pritchett, Saunders....980–5
(Instruments) Noncontacting Thickness Gauge Using Beta Rays. Clapp, Bernstein....488–90
Instruments, Principles of Design of Log-Scale D-C Indicating. Stimson, Taylor....1011–15
(Instruments) Resistance Wire Strain Gauges as Elements of the Wheatstone Bridge. Petrucelly..742–4
(Instruments) The Metrotype System of Digital Recording and Telemetering. Foster....543–6; disc. 546
(Instruments) The Theory of the Current Transductor and Its Application in the Aluminum Industry. Specht, Wagner....441–52; disc. 452
(Insulated Conductors) Development of Improved Luminous Sign Cable. Roehmann, Greenfield ....350–5; disc. 355
(Insulated Conductors) Heat Transfer Study on Power Cable Ducts and Duct Assemblies. Greebler, Barnett....357–64; disc. 364
(Insulated Conductors) The Thermal Resistance Between Cables and a Surrounding Pipe or Duct Wall. Buller, Neher....342–7; disc. 347
Insulation Caused by Soil Microorganisms, Failures of Rubber. Blake, Kitchin, Pratt..748–54; disc. 754
Insulation for Instrument Transformers, A New Dry-Type. Pfuntner, Franck, D'Entremont....453–8
Insulation Level, Co-ordination of Lightning Arrester Location with Transformer. Witzke, Bliss....964–73; disc. 973
Insulation Levels for High-Voltage Systems, Proposed Basic Impulse. Clem, Meador, Rudge, Powell ....953–60; disc. 960
Insulation Levels, Lightning Arresters as a Criterion for. Rorden....84–91; disc. 91
Insulation, Margins Between Lightning Arrester Protective Levels and Transformer. Vogel....110–12; disc. 112
Insulation of Traction Motor Field Coils, A New Resilient Class-H Material for the. Reed, Tyner....1158–61
Insulation Resistance on Energized Systems, Measurement of. Brancato, McClinton....1238–42
Integral Controller for Use in Carrier-Type Servomechanisms. Cosgriff....1379–83
Interconnecting Two or More Generating Systems, The Determination and Allocation of the Capacity Benefits Resulting from. Watchorn....1180–6
Interexchange Tandem Trunking in the Los Angeles Metropolitan Area. Pfeiffer....1071–9
Interference Filters, The Design of Reactors for Radio. Knudson....1294–8
Interrupting Ability of Horn-Gap Switches. Andrews, Jahn, Anderson....1016–24; disc. 1025
Interrupting Capacity at 600 Volts A-C, New Low-Voltage Air Circuit Breaker with 50,000 Ampere. Horn, Mikos....1654–7; disc. 1657
Interrupting Capacity, High-Voltage Oil Circuit Breakers for 5,000,000 to 10,000,000-Kva. Leeds, Friedrich....70–6; disc. 76
Interrupting Capacity Low-Voltage Power Fuse, A New High. Schuck....770–6; disc. 776
Inverter, An Amplistat Regulator Applied to a 5-Kva 400-Cycle Aircraft. Morgan, Walley....1243–8; disc. 1248
Investigation and Elimination of Unusual Vibration in the Field on a Large Single-Phase Frequency Changer. Ballantyne, Allen, Baudry....1264–72; disc. 1272
Investigation, Harmonic Index—A Tool for Transformer Audio Noise. Mutschler, Madden....115–18; disc. 118
Irradiation of Spark Gaps for Voltage Measurement, The. Hardy, Craggs....584–90

J

Joints for High Temperature Operation of Railway Traction Armatures, Solderless Commutator. Reed....638–41

L

(Land Transportation) A New Resilient Class-H Material for the Insulation of Traction Motor Field Coils. Reed, Tyner....1158–61
(Land Transportation) Control System for a 4,500-Horsepower Gas-Turbine Electric Locomotive. Warrick....508–13
(Land Transportation) Locomotive Wheel-Slip and Wheel-Lock Protection. Smith....1154–7
(Land Transportation) Rectifier-Type Motive Power for Railroad Electrification. Hibbard, Whittaker, Ames....519–23; disc. 523
(Land Transportation) Rotating Electric Equipment for A Gas-Turbine Electric Locomotive. Coho..514–18
(Land Transportation) Solderless Commutator Joints for High Temperature Operation of Railway Traction Armatures. Reed....638–41
(Land Transportation) The Alco-GE 4,500 Horsepower Gas-Turbine Electric Locomotive. Morey..504–07
Lead for A-C Servo Systems with Compensation for Carrier Frequency Changes, Phase. Nothoff ....285–91; disc. 291
Lead Length and Separation in Co-ordinated Protection of Apparatus Against Lightning, Evaluation of Lightning-Arrester. Carpenter, Johnson, Saline ....933–41; disc. 941
Lead Networks for Servomechanisms, Improvements in the Characteristics of A-C. McDonald....293–300
Level Considerations, Transformer Sound. Maslin. ....1142–5; disc. 1145
Level, Co-ordination of Lightning Arrester Location with Transformer Insulation. Witzke, Bliss....964–73; disc. 973
Levels and Transformer Insulation, Margins Between Lightning Arrester Protective. Vogel....110–12; disc. 112
Levels for High-Voltage Systems, Proposed Basic Impulse Insulation. Clem, Meador, Rudge, Powell ....953–60; disc. 960
Levels, Lightning Arresters as a Criterion for Insulation. Rorden....84–91; disc. 91
Life of Steel Strand, Vibration and Fatigue. Little, MacMillan, Majerczak....1473–8; disc. 1478
Light Steel Tower Line Design. Osipovich....1513–17; disc. 1517
Lightning-Arrester Lead Length and Separation in Co-ordinated Protection of Apparatus Against Lightning, Evaluation of. Carpenter, Johnson, Saline....933–41; disc. 941
Lightning Arrester Location with Transformer Insulation Level, Co-ordination of. Witzke, Bliss....964–73; disc. 973
Lightning Arrester Protective Levels and Transformer Insulation, Margins Between. Vogel....110–12; disc. 112
Lightning Arrester Standard, New. Stewart, Defandorf....525–6
Lightning Arresters as a Criterion for Insulation Levels. Rorden....84–91; disc. 91
Lightning Performance of Boulder 287.5-Kv Transmission Lines, Thirteen-Year. Blakeslee, Kanouse ....796–9; disc. 800
Lightning Performance of Transmission Lines, A Method of Estimating. (Committee Report)....1187–95; disc. 1195
Lightning Surges on Power Systems and Their Suppression, Some Aspects of. Kaneff....1544–9
Limit, Effect of Buck-Boost Voltage Regulator on Steady-State Power. Concordia..380–4; disc. 384
Limit Switch, An Environment-Free 120-Volt D-C High Performance. Stuelpnagel....1289–93
Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded Transmission Lines, Consideration of Requirements and. Parks, Brownlee....103–07; disc. 107
Line Design, Light Steel Tower. Osipovich....1513–17; disc. 1517
Line Protection of Short Lines of the Metropolitan Area of a Typical System, Transmission-. Marter ....468–71; disc. 471
Line Vibration, Use of Techniques from Electrical Analogues in the Study of Transmission. Lummis, Klopfenstein....1676–80
Linear Electronic Circuits, The Design of Broad-Band Transformers for. Lord....1005–10
Linearly Varying Elements, Stability of Servomechanisms with. Kirby....1662–7; disc. 1667
Lines, A Method of Estimating Lightning Performance of Transmission. (Committee Report)....1187–95; disc. 1195
Lines, Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily Loaded Transmission. Parks, Brownlee ....103–07; disc. 107
Lines of Short or Medium Length, An Improved Transmitted Carrier System for Telephone. Brooke 1501–04
Lines, Relay Protection for Medium Length High-Voltage Transmission. Klaghorn....461–5; disc. 465
Lines, Steady-State Waves on Transmission. Waidelich....1521–4
Lines, Thirteen-Year Lightning Performance of Boulder 287.5-Kv Transmission. Blakeslee, Kanouse....796–9; disc. 800
Liquid Cooling of A-C Turbine Generators. Part II. Fechheimer....165–71; disc. 171
(Part I–1947)
Load for Testing Rectifiers, Synthetic. Tetherow..642–4
Loading in Sealed Transformers, Variations of Tank Pressure with Transformer. Tipton....1669–73; disc. 1673
Loading of Hydrogen-Cooled Generators at Elevated Gas Pressures. Snell....186–99; disc. 199
Loads on Voltage Changes Produced by Single-Phase Loads, Effect of Three-Phase Motor. Faucett, Fisher, Helm....1467–72
Loads, Regulation of A-C Generators with Suddenly Applied. Part II. Harder, Cheek, Clayton....395–405; disc. 405
(Part I–1944)
Local Wire Video Television Networks. Nebel..1451–60
Lock Protection, Locomotive Wheel-Slip and Wheel-Smith....1154–7
Locomotive, Control System for a 4,500-Horsepower Gas-Turbine Electric. Warrick....508–13
Locomotive, Rotating Electric Equipment for a Gas-Turbine Electric. Coho....514–18
Locomotive, The Alco-GE 4,500-Horsepower Gas-Turbine Electric. Morey....504–07
Locomotive Wheel-Slip and Wheel-Lock Protection. Smith....1154–7
Locus Method, Control System Synthesis by Root. Evans....66–9
Log Carriage Drive, Amplidyne-Controlled. Vincent ....1124–9; disc. 1129
Log-Scale D-C Indicating Instruments, Principles of Design of. Stimson, Taylor....1011–15
Long-Distance Power Transmission. Crary....834–40; disc. 840
Los Angeles Metropolitan Area, Interexchange Tandem Trunking in the. Pfeiffer....1071–9
Los Angeles, Power System Planning in the City of. Williams, Kanouse....900–07; disc. 907
Loss on Conductors for Operation Above 230 Kv, Desert Measurements of Corona. Peterson, Cozzens, Carroll....872–8; disc. 878
Losses in Power Transmission Networks, Total and Incremental. Ward, Eaton, Hale..626–31; disc. 631
Low Impedance, Series-Connected Saturable Reactor with Control Source of Comparatively. Storm 756–65
Low Speeds, Synchronous Machine Damping Torque at. Concordia....1550–3

Low-Voltage Air Circuit Breaker with 50,000 Ampere Interrupting Capacity at 600 Volts A-C, New. Horn, Mikos....1654–7; disc. 1657
Low-Voltage Air Circuit Breakers, An Air Delayed Selective Overcurrent Tripping Device for. Tremblay, Horn....1649–53
Low-Voltage Power Fuse, A New High-Interrupting Capacity. Shuck....770–6; disc. 776
Luminous Sign Cable, Development of Improved. Roehmann, Greenfield....350–5; disc. 355

Machine Short Circuits, Analysis of Synchronous. Camburn, Gross....671–8; disc. 678
Machines and Their Application, Spring and Damping Coefficients of Synchronous. Kilgore, Whitney....226–9; disc. 229
Machines, Per-Unit Inductances of Synchronous. Kirschbaum....231–4
Machines, Power Reactance for Salient-Pole Synchronous. Mikhail....235–8
Machines, Surface Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric. Snell, Norris, Buckland....174–85; disc. 185
Magnetic Amplifier Frequency Control, A. Johnson, Schafer....613–15
Magnetic Amplifiers, An Analysis of Transients and Feedback in. Johnson, Latson....604–11; disc. 611
Magnetic Amplifiers, An Analysis of Transients in. VerPlanck, Finzi, Beaumariage....498–503
Magnetic Amplifiers, Determination of Steady-State Performance of Self-Saturating. Smith....1309–17
Magnetic Amplifiers, General Characteristics of. Finzi, Beaumariage....919–27
Magnetic Amplifiers, Response Time of. Harder, Horton....1130–8; disc. 1138
Magnetic-Fluid Clutch Servomechanisms, Characteristics of Some. Parziale, Tilton....150–7
Magnets, The Operating Speed of D-C Brake. Ryan, Spitler....1253–7
Main Power Transformers for Generating Stations, The Choice of. Dillow, Butler....781–5; disc. 785
Manholes, Critical Inside Dimensions for Power Cable. Halfmann....1576–80; disc. 1580
Manufacturer's Viewpoint, Aluminum Conductors from an Aircraft. Schumacher....1335–41
Mappers, The Further Development of Fluid. Moore....1615–24
Margins Between Lightning Arrester Protective Levels and Transformer Insulation. Vogel....110–12; disc. 112
Maximum Short-Circuit Current of D-C Motors and Generators. (Committee Report)....146–9
Mean Distances, Transpositions and the Calculation of Inductance from Geometric. Boast....1531–4
Measurement and Calculation of D-C Machine Armature Circuit Inductance. Snively, Robinson....1228–35; disc. 1235
Measurement by the Hook-on Method, Power. Corson, Nylander....699–702
Measurement of Bandwidth, The Direct. Ammerman....27–31
Measurement of Insulation Resistance on Energized Systems. Brancato, McClinton....1238–42
Measurement, The Irradiation of Spark Gaps for Voltage. Hardy, Craggs....584–90
Measurements by Repeated Structure Networks, Impulse. Dawes, Thomas, Drought....571–80; disc. 580
Measurements of Corona Loss on Conductors for Operation Above 230 Kv, Desert. Peterson, Cozzens, Carroll....872–8; disc. 878
Measurements on Polyphase and Multiconductor Cable Using Single-Phase Bridges, Power Factor. Greenfield....680–5; disc. 685
Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An Improved Method of. Miller, Whelan....491–7
Measuring the Ratio and Phase Angle of Current Transformers, A Primary Method of. Brownlee....459–60
Mechanisms, Electrode Control and Associated Operating. Hanff....567–70; disc. 570
Media Separation Process, Electric Equipment for Heavy-. Bean, Blind....1421–9
Medical Research, Electrical Instrumentation in. Benjamin, Hale, Carstensen, Tompkins....1324–7
Medium-Haul Carrier Telephone System, A. Smith....1505–12
Megacycles, Microwave Systems for 960 and 2,000. Rector, Sutter....1100–08; disc. 1108
Message Accounting System, Fundamentals of the Automatic Telephone. Meszar....255–68; disc. 269
Metal-Clad Switchgear, A New Grounding and Testing Device for. Krida, McCurry....407–12; disc. 412
Metal-Clad Switchgear Serving Oil Refinery Motors During Power System Disturbances, Automatic Control of. Horsfall, Thompson, Mills, Bobo....1600–03; disc. 1603
(Metal) Electric Equipment for Heavy-Media Separation Process. Bean, Blind....1421–9
Meter, A Voltage Gradient. Tremaine, Cheek....633–7; disc. 637
Metering Purposes, A Survey of Bushing-Type Current Transformers for. Camilli....429–40
Meters, A New Device for Calibrating Watt-Hour. Robison, Wickham....732–4
Method, Control System Synthesis by Root Locus. Evans....66–9
Method, Determination of Reserve Capacity by the Probability. Calabrese....1681–8; disc. 1688
Method for Analyzing and Synthesizing Contactor Servomechanisms, A Frequency Response. Kochenburger....270–83; disc. 283
Method of Estimating Lightning Performance of Transmission Lines, A. (Committee Report)....1187–95; disc. 1195
Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation Principle, An Improved. Miller, Whelan....491–7
Method of Measuring the Ratio and Phase Angle of Current Transformers, A Primary. Brownlee....459–60
Method of Total Design as Applied to Polyphase Induction Motors, A. Crouse....1434–7
Method, Power Measurement by the Hook-On. Corson, Nylander....699–702
Metropolitan Area of a Typical System, Transmission-Line Protection of Short Lines of the. Marter....468–71; disc. 471
Metrotype System of Digital Recording and Telemetering, The. Foster....543–6; disc. 546
Microorganisms, Failures of Rubber Insulation Caused by Soil. Blake, Kitchin, Pratt....748–54; disc. 754
Microwave Applications to Bonneville Power Administration System. Stevens, Stringfield....1088–99
Microwave Channel for Voice Communication, Relaying, Telemetering, and Supervisory Control, Field Testing a. Pattison, Reagan, Leyland, Gunter....945–51; disc. 951
Microwave Systems for 960 and 2,000 Megacycles. Rector, Sutter....1100–08; disc. 1108
Mills, Basic Patterns for Arrangement of Electric Power Systems for Steel. Finison....54–9; disc. 59
Modern Carrier Current Test Equipment and Its Application. Brinton....777–80
Motive Power for Railroad Electrification, Rectifier-Type. Hibbard, Whittaker, Ames....519–23; disc. 523
Motor-Driven Exciters, Excitation System Performance with. Mellor, Temoshok....321–7
Motor Drives, Rectifier Equipment for Electronic D-C. Mulhern, Crawford....211–15
Motor Drives to Printing Presses, Application of Electronic. Johnson, Stacey....216–19
Motor Field Coils, A New Resilient Class-H Material for the Insulation of Traction. Reed, Tyner....1158–61
Motor Loads on Voltage Changes Produced by Single-Phase Loads, Effect of Three-Phase. Faucett, Fisher, Helm....1467–72
Motor with Space Harmonics, Equivalent Circuits of the Shaded-Pole. Kron....735–41
Motors—A Design Method, A-C Series. Chang, Karr....1257–61; disc. 1261
Motors, A Method of Total Design as Applied to Polyphase Induction. Crouse....1434–7
Motors and Generators, Maximum Short-Circuit Current of D-C. (Committee Report)....146–9
Motors During Power System Disturbances, Automatic Control of Metal-Clad Switchgear Serving Oil Refinery. Horsfall, Thompson, Mills, Bobo....1600–03; disc. 1603
Motors, Generator Rating of Induction. Smith....129–35
Motors Need Test Equipment, Aircraft Electric. Ross....1359–64
Motors, Suggested Improvements in the Performance Calculations of Single-Phase Induction. Thacker, Gopalakrishna....1–6; disc. 6
Motors Supplied from Ignitron Rectifiers, Control of Large D-C. Livingston....205–10
Motors with Unbalanced Rotor Impedances, The Goerges Phenomenon—Induction. Garbarino, Gross....1562–74; disc. 1574
Multicomponent Fractionation Calculations, Analogue Computer for. Goela, Calvert....97–103
Multiconductor Cable Using Single-Phase Bridges, Power Factor Measurements on Polyphase and. Greenfield....680–5; disc. 685
Multiplexing Equipment with High Stability Carrier Supply, A Low Noise and Distortion Audio. Beale....1028–37; disc. 1037
Multistation Supervisory Control, Telemetering, and Communication on Single-Frequency Carrier Channel. Derr, Wren, Kresser....1115–21; disc. 1121

N

Nature and Physical Concepts of Thyratron Deionization Time, Statistical. Romanowitz, Dow....368–79
Negative Impedance Repeater, A. Merrill....1461–6
Networks for Servomechanisms, Improvements in the Characteristics of A-C Lead. McDonald....293–300
Networks, Impulse Measurements by Repeated Structure. Dawes, Thomas, Drought....571–80; disc. 580
Networks, Local Wire Video Television. Nebel....1451–60
Networks, Total and Incremental Losses in Power Transmission. Ward, Eaton, Hale....626–31; disc. 631
Neutral Grounding Devices, Development of the Standard for. Clem....976–9
Neutral Potentials, Rural. Waghorne....660–3; disc. 663
New Lightning Arrester Standard. Stewart, Defandorf....525–6
New Line of Orthomagnetic Bushing-Type Current Transformers, A. Farr....424–8
New 69-Kv Oil Blast Circuit Breaker, A. Rietz, Balentine....416–23; disc. 423
New Techniques on the Anacom—Electric Analog Computer. Harder, Carleton....547–56
Noise and Distortion Audio Multiplexing Equipment with High Stability Carrier Supply, A Low. Beale....1028–37; disc. 1037
Noise and Its Confinement, Transformer. McLean....1409–15; disc. 1415
Noise in Transformers in Residential and Commercial Areas, Audio. Baugh....121–6; disc. 126
Noise Investigation, Harmonic Index—A Tool for Transformer Audio. Mutschler, Madden....115–18; disc. 118
Noise of Power Transformers, Audible. Gordy....45–50; disc. 50
Noise on Aircraft, Tracking Radio. Owen....1249–52
Noncontacting Thickness Gauge Using Beta Rays. Clapp, Bernstein....488–90
Nonlinear Element, An Electric Analogue Computer Using the Photo Cell as a. Koenig....1606–11
Nonlinear Servomechanisms, An Electronic Simulator for. Edwards, Johnson....300–05; disc. 306
Number 5 Crossbar Dial Telephone Switching System, The. Korn, Ferguson....244–54

O

Office Buildings for Small Communities, Dial Telephone Central. Reese, Roys....1535–9
Office Equipment, General Aspects of Community Dial. Burkett....1540–3
Officers and Committees for 1950–51....1717–36
Offices, Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial. Brooke, Blackhall, Blashfield....1417–20
Oil Blast Circuit Breaker, A New 69-Kv. Rietz, Balentine....416–23; disc. 423
Oil Circuit Breakers for 5,000,000 to 10,000,000-Kva Interrupting Capacity, High-Voltage. Leeds, Friedrich....70–6; disc. 76
Oil Refinery Motors During Power System Disturbances, Automatic Control of Metal-Clad Switchgear Serving. Horsfall, Thompson, Mills, Bobo....1600–03; disc. 1603
Oil Temperature in a Transformer, Determination of Effective. Beavers....703–08; disc. 708
Oil, Transformers. Treanor, Raab....1060–70; disc. 1070
Operating Mechanisms, Electrode Control and Associated. Hanff....567–70; disc. 570
Operating Speed of D-C Brake Magnets, The. Ryan, Spitler....1253–7
Operation of Central Control Rooms, Design and. Borgel....598–602; disc. 602
Operation of Graphitizing Furnaces, Electric Equipment and. Cole....563–6
Operation of Power Transformers on American Gas and Electric Company System, Selection, Design, and. Lane, Gross, Pugh....786–93; disc. 793
Operation of Railway Traction Armatures, Solderless Commutator Joints for High Temperature. Reed....638–41
Orthomagnetic Bushing-Type Current Transformers, A New Line of. Farr....424–8
Outdoor Disconnecting Switches to Simulate Field Conditions, Ice Testing of. Owens....1488–91; disc. 1491
Overcurrent Tripping Device for Low-Voltage Air Circuit Breakers, An Air Delayed Selective. Tremblay, Horn....1649–53

P

Paper Cables, Terminal Risers for Solid-Type Impregnated. Del Mar.....1592-7; disc. 1597
Particle Accelerators, Ignitron Converters for High Energy. Boyer, Marcum.....1110-14
Particle Accelerators, Ignitron Pulse Equipment for. Herskind, Hudson.....992-6
Patterns for Arrangement of Electric Power Systems for Steel Mills, Basic. Finison.....54-9; disc. 59
Per-Unit Inductances of Synchronous Machines. Kirschbaum.....231-4
Perception Currents, Effect of Frequency on. Dalziel, Mansfield.....1162-8
Performance by A-C Components, The Extension of Amplistat. Morgan, Ogle, Wattenberger...986-91
Performance Calculations of Single-Phase Induction Motors, Suggested Improvements in the. Thacker, Gopalakrishna.....1-6; disc. 6
Performance of Low-Voltage, An Environment-Free 120-Volt D-C High. Stuelpnagel.....1289-93
Performance of Boulder 287.5-Kv Transmission Lines, Thirteen-Year Lightning. Blakeslee, Kanouse.....796-9; disc. 800
Performance of Self-Saturating Magnetic Amplifiers, Determination of Steady-State. Smith.....1309-17
Performance of the Selsyn Generator Control Transformer System, Static Accuracy. Kronacher.....645-53; disc. 653
Performance of Transmission Lines, A Method of Estimating Lightning. (Committee Report).....1187-95; disc. 1195
Performance with Motor-Driven Exciters, Excitation System. Mellor, Temoshok.....321-7
Phase and Ground Distance Relaying, Combined. New.....37-42; disc. 42
Phase Angle of Current Transformers, A Primary Method of Measuring the Ratio and. Brownlee.....459-60
Phase Lead for A-C Servo Systems with Compensation for Carrier Frequency Changes. Nottbolf.....285-91; disc. 291
Phase Relays, A Study of Directional Element Connections for. Sonnemann.....1438-50; disc. 1450
Phenomenon—Induction Motors with Unbalanced Rotor Impedances, The Goerges. Garbarino, Gross.....1569-74; disc. 1574
Photo Cell as a Nonlinear Element, An Electric Analogue Computer Using the. Koenig.....1606-11
Physical Concepts of Thyratron Deionization Time, Statistical Nature and. Romanowitz, Dow.....368-79
Pile Voltage Regulators, Dynamic Characteristics of Carbon. Mills.....1347-52; disc. 1352
Pipe or Duct Wall, The Thermal Resistance Between Cables and a Surrounding. Buller, Neher.....342-7; disc. 347
Planning in the City of Los Angeles, Power System. Williams, Kanouse.....900-07; disc. 907
Plants, Centralized Control Board for Steam-Electric Generating. Lowe, Hodgkins...1396-9; disc. 1399
Plants, Underground Hydroelectric Power. Gisiger.....1169-75
Pole Motor with Space Harmonics, Equivalent Circuits of the Shaded-. Kron.....735-41
Pole Synchronous Machines, Potier Reactance for Salient. Mikhail.....235-8
Polyphase and Multiconductor Cable Using Single-Phase Bridges, Power Factor Measurements on. Greenfield.....680-5; disc. 685
Polyphase Induction Motors, A Method of Total Design as Applied to. Crouse.....1434-7
Polyphase Rectifiers, Effects of Supply Line Unbalance on the Filtered Output Ripple of. Hooper, McAdie.....766-70
Potentials, Rural Neutral. Waghorne...660-3; disc. 663
Potier Reactance for Salient-Pole Synchronous Machines. Mikhail.....235-8
Power Arcs in Large Air Gaps, Dielectric Recovery Characteristics of. McCann, Conner, Ellis.....616-24; disc. 624
Power Cable Ducts and Duct Assemblies, Heat Transfer Study on. Greebler, Barnett.....357-64; disc. 364
Power Cable Manholes, Critical Inside Dimensions for. Halfmann.....1576-80; disc. 1580
Power Converters, Protection of Electronic. (Committee Report).....813-29
Power Factor Measurements on Polyphase and Multiconductor Cable Using Single-Phase Bridges. Greenfield.....680-5; disc. 685
Power for Railroad Electrification, Rectifier-Type Motive. Hibbard, Whittaker, Ames...519-23; disc. 523
Power Fuse, A New High Interrupting Capacity Low-Voltage. Schuck.....770-6; disc. 776
(Power Generation) Bus Transfer Tests on 2,300-Volt Station Auxiliary System. Johnson, Thompson.....386-90; disc. 390
Power Generation, Control of Gas Turbines for. Hoffmann, Mellor, Starkey.....1637-41; disc. 1641
(Power Generation) Design and Operation of Central Control Rooms. Borgel.....597-602; disc. 602
(Power Generation) Design and Test on Electronic Exciter Supplied from Common Shaft-Driven Generator. Colalaco, Johnson, Reilly...328-35; disc. 335
(Power Generation) Excitation Improvement—Electronic Excitation and Regulation of Electric Generators as Compared to Conventional Methods. Phillips, Lambert, Pattison.....338-40; disc. 340
(Power Generation) Excitation System Performance with Motor-Driven Exciters. Mellor, Temoshok.....321-7
(Power Generation) Hydroelectric Generator Excitation Experience at Grand Coulee. Killgore, Holmdahl.....855-60
(Power Generation) Induced Currents in High-Capacity Bus Enclosures. Killian.....1388-95; disc. 1395
(Power Generation) Regulation of A-C Generators with Suddenly Applied Loads. Part II. Harder, Cheek Clayton...395-405; disc. 405 (Part I-1944)
(Power Generation) The Bridge River Hydroelectric Development. Ingledow, Steede.....845-54
Power Limit, Effect of Buck-Boost Voltage Regulator on Steady-State. Concordia.....380-4; disc. 384
Power Measurement by the Hook-On Method. Corson, Nylander.....698-702
Power Plants, Underground Hydroelectric. Gisiger.....1169-75
Power Stations, Centralized Instrumentation and Controls for Steam Electric. Mallory...591-6; disc. 596
Power Stations in Sweden, Underground Hydroelectric. Ruseck, Westerberg.....928-32
Power System Disturbances, Automatic Control of Metal-Clad Switchgear Serving Oil Refinery Motors During. Horsfall, Thompson, Mills, Bobo.....1600-03; disc. 1603
Power System Planning in the City of Los Angeles. Williams, Kanouse.....900-07; disc. 907
Power Systems and Their Suppression, Some Aspects of Lightning Surges on. Kaneff.....1544-9
Power Systems for Steel Mills, Basic Patterns for Arrangement of Electric. Finison.....54-9; disc. 59
Power Systems—Fundamentals and Basic Design Considerations, Underground Conduit for Electric. Watkins.....1582-90; disc. 1590
Power Transformer Formed Cores, Single-Phase. Gordy, Somerville.....1384-7
Power Transformers, Audible Noise of. Gordy.....45-50; disc. 50
Power Transformers for Generating Stations, The Choice of Main. Dillow, Butler.....781-5; disc. 785
Power Transformers for Use on the Systems of the Hydro-Electric Power Commission of Ontario, Contributing Factors in Determining the Ratings of. Fleming, Lotimer.....1658-62; disc. 1662
Power Transformers on American Gas and Electric Company System, Selection, Design, and Operation of. Lane, Gross, Pugh.....786-93; disc. 793
Power Transformers on the System of the Bonneville Power Administration, Application and Handling of Very Large. Stevens.....158-63; disc. 163
Power Transformers, Selection and Application of. Seelye.....830-3
Power Transmission, Long-Distance. Crary.....834-40; disc. 840
Power Transmission Networks, Total and Incremental Losses in. Ward, Eaton, Hale...626-31; disc. 631
Practical Experiences with Resonant Grounding in a Large 34.5-Kv System. Brown, Gross.....1401-06; disc. 1406
Practices and Economical Switching Station Arrangements of the Bureau of Reclamation, Relaying. Morgan, World.....865-70; disc. 870
Premises, Protective Grounding of Electrical Installations on Customer's. Schirmer.....657-9
Presses, Application of Electronic Motor Drives to Printing. Johnson, Stacey.....216-19
Pressure with Transformer Loading in Sealed Transformers, Variations of Tank. Tipton.....1669-73; disc. 1673
Pressures, Loading of Hydrogen-Cooled Generators at Elevated Gas. Snell.....186-99; disc. 199
Primary Method of Measuring the Ratio and Phase Angle of Current Transformers, A. Brownlee.....459-60
Principle, An Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance Variation. Miller, Whelan.....491-7
Principles of Design of Log-Scale D-C Indicating Instruments. Stimson, Taylor.....1011-15
Printing Presses, Application of Electronic Motor Drives to. Johnson, Stacey.....216-19
Printing Telegraph Tape-to-Page Translator, A. Frost.....79-83
Probability Method, Determination of Reserve Capacity by the. Calabrese.....1681-8; disc. 1688
Problems and Their Solution on Turbine-Generator Units and Auxiliaries of the Consolidated Edison System, Thrust Bearing. Driscoll, Otten.....1642-7; disc. 1647
Problems, Special Devices Aid Differential Analyzer Solution of Complex. Cook, Kirchmayer, Weygandt.....1365-70; disc. 1370
Process, Electric Equipment for Heavy-Media Separation. Bean, Blind.....1421-9
Production Testing on Large D-C Apparatus, Quick and Accurate. Baldwin, Barnhart.....136-8
Program, The Bonneville Power Administration Relaying and Reclosing. Diemond, Wylie.....1039-46; disc. 1046
Progress Report on Tidd 500-Kv Test Project of the American Gas and Electric Company—Corona, Radio Influence, and Other Factors. Sporn, Monteith.....891-7; disc. 897
Proposed Basic Impulse Insulation Levels for High Voltage Systems. Clem, Meador, Rudge, Powell.....953-60; disc. 960
Protection for Medium Length High-Voltage Transmission Lines, Relay. Kinghorn...461-5; disc. 465
Protection, Locomotive Wheel-Slip and Wheel-Lock. Smith.....1154-7
Protection of Apparatus Against Lightning, Evaluation of Lightning-Arrester Lead Length and Separation in Co-ordinated. Carpenter, Johnson, Saline.....933-41; disc. 941
Protection of Cable-Connected Equipment, Surge. Witzke, Bliss.....527-38; disc. 539
Protection of Electronic Power Converters. (Committee Report).....813-29
Protection of Short Lines of the Metropolitan Area of a Typical System, Transmission-Line. Marter.....468-71; disc. 471
Protection, Sensitive Ground. (Committee Report).....473-5; disc. 475
Protection, Theory and Application of Transformer Differential. McKenna.....1197-1202
(Protective Devices) Co-ordination of Lightning Arrester Location with Transformer Insulation Level. Witzke, Bliss.....964-73; disc. 973
(Protective Devices) Development of the Standard for Neutral Grounding Devices.....976-9
(Protective Devices) Lightning Arresters as a Criterion for Insulation Levels. Rorden.....84-91; disc. 91
(Protective Devices) New Lightning Arrester Standard. Stewart, Defandorf.....525-6
(Protective Devices) Practical Experiences With Resonant Grounding in a Large 34.5-Kv System. Brown, Gross.....1401-06; disc. 1406
Protective Grounding of Electrical Installations on Customer's Premises. Schirmer.....657-9
Protective Levels and Transformer Insulation, Margins Between Lightning Arrester. Vogel.....110-12; disc. 112
Pulse Equipment for Particle Accelerators, Ignitron. Herskind, Hudson.....992-6

Q

Quiet Transformer Installations—A Problem for Both Equipment and Substation Designers. Mendenhall, Taylor.....1148-52; disc. 1152

R

Radio Influence, and Other Factors, Progress Report on Tidd 500-Kv Test Project of the American Gas and Electric Company—Corona. Sporn, Monteith.....891-7; disc. 897
Radio Interference Filters, The Design of Reactors for. Knudson.....1294-8
Radio Noise on Aircraft, Tracking. Owen.....1249-52
Railroad Electrification, Rectifier-Type Motive Power for. Hibbard, Whittaker, Ames...519-23; disc. 523
Railway Traction Armatures, Solderless Commutator Joints for High Temperature Operation of. Reed.....638-41
Range A-C Electric Systems for Aircraft, Wide Speed. James, Judkins, Merahon.....1353-8; disc. 1358
Rate Low-Density Toll Circuits Between Community Dial Offices, Simplified Subscriber Toll Dialing for Low-. Brooke, Blackhall, Blashfield.....1417-20
Rating of Induction Motors, Generator. Smith...129-35
Ratings for Transformers, Development of Preferred Voltage. St. Clair, Jalonack...1049-59; disc. 1059
Ratings of Power Transformers for Use on the Systems of the Hydro-Electric Power Commission of Ontario, Contributing Factors in Determining the. Fleming, Lotimer.....1658-62; disc. 1662
Ratio and Phase Angle of Current Transformers, A Primary Method of Measuring the. Brownlee.....459-60
Rays, Noncontacting Thickness Gauge Using Beta. Clapp, Bernstein.....488-90
Reactance for Salient-Pole Synchronous Machines, Potier. Mikhail.....235-8
Reactor with Control Source of Comparatively High Impedance, Series-Connected Saturable. Storm.....1299-1309
Reactor with Control Source of Comparatively Low Impedance, Series Connected Saturable. Storm.....756-65
Reactors for Radio Interference Filters, The Design of. Knudson.....1294-8

Reading High-Voltage Capacitance Bridge, A Direct. Foley ..... 692–8; disc. 698
Receiver, A New Electronic Telegraph Regenerative. Ostendorf ..... 32–6; disc. 36
Reclosing on Long and Heavily Loaded Transmission Lines, Consideration of Requirements and Limitations of Relaying and High-Speed. Parks, Brownlee ..... 103–07; disc. 107
Reclosing Program, The Bonneville Power Administration Relaying and. Diemond, Wylie ..... 1039–46; disc. 1046
Reclosing Relay, An Improved. Goff ..... 1480–4; disc. 1484

Servomechanisms, An Electronic Simulator for Nonlinear. Edwards, Johnson ..... 300–06; disc. 306
Servomechanisms, Characteristics of Some Magnetic-Fluid Clutch. Parziale, Tilton 150–7
Servomechanisms, Improvements in the Characteristics of A-C Lead Networks for. McDonald 293–300
Servomechanism, Integral Controller for Use in Carrier-Type. Cosgriff 1379–83
Servomechanisms with Linearly Varying Elements, Stability of. Kirby ..... 1662–7; disc. 1667
Shaded-Pole Motor with Space Harmonics, Equivalent Circuits of the. Kron 735–41
Shaft-Driven Generator, Design and Test of Electronic Exciter Supplied from Common. Colaizzo, Johnson, Reilly ..... 328–35; disc. 335
Short-Circuit Current of D-C Motors and Generators, Maximum. (Committee Report) 146–9
Short Circuits, Analysis of Synchronous Machine. Camburn, Gross ..... 671–6; disc. 678
Short Circuits on Saturated Alternators, Symmetrical. Mikhail 1554–62
Short Lines of the Metropolitan Area of a Typical System, Transmission-Line Protection of. Marter ..... 468–71; disc. 471
Sign Cable, Development of Improved Luminous. Roehmann, Greenfield ..... 350–5; disc. 355
Simplified 48-Channel Carrier Telephone System, A. Erickson 1493–1500
Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial Offices. Brooke, Blackhall, Blashfield 1417–20
Simulation, A Generalized Analogue Computer for Flight. Hall 308–20
Simulator for Nonlinear Servomechanisms, An Electronic. Edwards, Johnson ..... 300–06; disc. 306
Single-Phase Frequency Changer, Investigation and Elimination of Unusual Vibration in the Field on a Large. Ballantyne, Allen, Baudry ..... 1264–72; disc. 1272
Single-Phase Induction Motors, Suggested Improvements in the Performance Calculations of. Thacker, Gopalakrishna ..... 1–6; disc. 6
Single-Phase Loads, Effect of Three-Phase Motor Loads on Voltage Changes Produced by. Faucett, Fisher, Helm 1467–72
Single-Phase Power Transformer Formed Cores. Gordy, Somerville 1384–7
Soil Microorganisms, Failures of Rubber Insulation Caused by. Blake, Kitchin, Pratt ..... 748–54; disc. 754

Solderless Commutator Joints for High Temperature Operation of Railway Traction Armatures. Reed for. Del Mar 638–41
Solid-Type Impregnated Paper Cables, Terminal Risers for. Del Mar ..... 1592–7; disc. 1597
Solution of Complex Problems, Special Devices Aid Differential Analyzer. Cook, Kirchmayer, Weygandt ..... 1365–70; disc. 1370
Some Aspects of Lightning Surges on Power Systems and their Suppression. Kaneff 1544–9
Sound Level Considerations, Transformer. Maslin ..... 1142–5; disc. 1145
Source of Comparatively High Impedance, Series-Connected Saturable Reactor with Control. Storm 1299–1309
Source of Comparatively Low Impedance, Series-Connected Saturable Reactor with Control. Storm 756–65
Southern California Edison Company, Expansion of the System of the. Kroneberg 861–4
Spark Gaps for Voltage Measurement, The Irradiation of. Hardy, Craggs 584–90
Special Devices Aid Differential Analyzer Solution of Complex Problems. Cook, Kirchmayer, Weygandt ..... 1365–70; disc. 1370
Speed Drive Constant Frequency Alternator, Variable. Gould, Krupotich ..... 745–7; disc. 747
Speed of D-C Brake Magnets, The Operating. Ryan, Spitler 1253–7
Speed Range A-C Electric Systems for Aircraft, Wide. James, Judkins, Mershon ..... 1353–8; disc. 1358
Speeds, Synchronous Machine Damping Torque at Low. Concordia 1550–3
Spring and Damping Coefficients of Synchronous Machines and Their Application. Kilgore, Whitney ..... 226–9; disc. 229
Stability of Servomechanisms with Linearly Varying Elements. Kirby ..... 1662–7; disc. 1667
Stability of Voltage Regulators. Bothwell ..... 1430–3; disc. 1433
Standard for Neutral Grounding Devices, Development of the. Clem 976–9
Standard, New Lightning Arrester. Stewart, Defandorf 525–6
State Waves on Transmission Lines, Steady-. Waudelich 1521–4
Static Accuracy Performance of the Selsyn Generator Control-Transformer System. Kronacher ..... 645–53; disc. 653
Station Arrangements of the Bureau of Reclamation, Relaying Practices and Economical Switching. Morgan, World ..... 865–70; disc. 870
Station Auxiliary System, Bus Transfer Tests on 2,300-Volt. Johnson, Thompson ..... 386–90; disc. 390
Stations, Automatic Control of Ignitron Rectifier. Chaney, Derr ..... 801–11; disc. 811
Stations, Centralized Instrumentation and Controls for Steam Electric Power. Mallory ..... 591–6; disc. 596
Stations, The Choice of Main Power Transformers for Generating. Dillow, Butler ..... 781–5; disc. 785
Statistical Nature and Physical Concepts of Thyratron Deionization Time. Romanowitz, Dow 368–79
Steady-State Performance of Self-Saturating Magnetic Amplifiers, Determination of. Smith 1309–17
Steady-State Power Limit, Effect of Buck-Boost Voltage Regulator on. Concordia ..... 380–4; disc. 384
Steady-State Waves on Transmission Lines. Waudelich 1521–4
Steam-Electric Generating Plants, Centralized Control Board for. Lowe, Hodgkins ..... 1396–9; disc. 1399
Steam Electric Power Stations, Centralized Instrumentation and Controls for. Mallory ..... 591–6; disc. 596
Steel Mills, Basic Patterns for Arrangement of Electric Power Systems for. Finison ..... 54–9; disc. 59
Steel Strand, Vibration and Fatigue Life of. Little, MacMillan, Majercak ..... 1473–8; disc. 1478
Steel Tower Line Design, Light. Osipovich ..... 1513–17; disc. 1517
Strain Gauges as Elements of the Wheatstone Bridge, Resistance Wire. Petrucelly 742–4
Strand, Vibration and Fatigue Life of Steel. Little, MacMillan, Majercak ..... 1473–8; disc. 1478
Strowger Automatic Telephone Systems, The Universal Director in. Ostline 1080–7
Structure Networks, Impulse Measurements by Repeated. Dawes, Thomas, Drought ..... 571–80; disc. 580
Study of Directional Element Connections for Phase Relays, A. Sonnemann ..... 1438–50; disc. 1450
Study of Transmission Line Vibration, Use of Techniques from Electrical Analogues in the. Lummis, Klopfenstein 1676–80
Study of Turbine Generator Rotor Ventilation, An Experimental and Analytical. Fechheimer 1563–9
Study on Power Cable Ducts and Duct Assemblies, Heat Transfer. Greebler, Barnett ..... 357–64; disc. 364
Submarine Cables, A Two-Channel Carrier Telegraph System for Short. Newell, Cramer 61–5
Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial Offices, Simplified. Brooke, Blackhall, Blashfield 1417–20
Substation, A 5,000-Kva Underground. Sinnott ..... 882–9; disc. 889
Substation Designers, Quiet Transformer Installations—A Problem for Both Equipment and. Mendenhall, Taylor ..... 1148–52; disc. 1152
Suddenly Applied Loads, Regulation of A-C Generators with. Part II. Harder, Cheek, Clayton ..... 395–405; disc. 405
(Part I—1944)
Suggested Improvements in the Performance Calculations of Single-Phase Induction Motors. Thacker, Gopalakrishna ..... 1–6; disc. 6
Supervisory Control, Field Testing a Microwave Channel for Voice Communication, Relaying, Telemetering and. Pattison, Reagan, Leyland, Gunter ..... 945–51; disc. 951
Supervisory Control, Telemetering, and Communication on Single-Frequency Carrier Channel, Multistation. Derr, Wren, Kresser ..... 1115–21; disc. 1121
Supply, A Low Noise and Distortion Audio Multiplexing Equipment with High Stability Carrier. Beale ..... 1028–37; disc. 1037
Supply Line Unbalance on the Filtered Output Ripple of Polyphase Rectifiers, Effects of. Hooper, McAdie 766–70
Surface Resistance Coefficients for Hydrogen-Cooled Rotating Electric Machines. Snell, Norris, Buckland ..... 174–85; disc. 185
Surge Protection of Cable-Connected Equipment. Witzke, Bliss ..... 527–38; disc. 539
Surges on Power Systems and Their Suppression, Some Aspects of Lightning. Kaneff 1544–9
Survey of Bushing-Type Current Transformers for Metering Purposes, A. Camilli 429–40
Sweden, Underground Hydroelectric Power Stations in. Ruack, Westerberg 928–32
Switch, An Environment-Free 120-Volt D-C High Performance Limit. Stuelpnagel 1289–93
Switches, Interrupting Ability of Horn-Gap. Andrews, Janes, Anderson ..... 1016–24; disc. 1025
Switches to Simulate Field Conditions, Ice Testing of Outdoor Disconnecting. Owens ..... 1488–91; disc. 1491
Switchgear, A New Grounding and Testing Device for Metal-Clad. Krida, McCurry ..... 407–12; disc. 412
(Switchgear) A New High Interrupting Capacity Low-Voltage Power Fuse. Schuck ..... 770–6; disc. 776
(Switchgear) A New 69-Kv Oil Blast Circuit Breaker. Rietz, Balentine ..... 416–23; disc. 423
(Switchgear) An Air Delayed Selective Overcurrent Tripping Device for Low-Voltage Air Circuit Breakers. Tremblay, Horn 1649–53
(Switchgear) Development and Testing of an Improved High-Voltage, High-Capacity Impulse Circuit Breaker. Rietz ..... 15–25; disc. 25
Switchgear Serving Oil Refinery Motors During Power System Disturbances, Automatic Control of Metal-Clad. Horsfall, Thompson, Mills, Bobo ..... 1600–03; disc. 1603
Switching Station Arrangements of the Bureau of Reclamation, Relaying Practices and Economical. Morgan, World ..... 865–70; disc. 870
Switching System, The Number 5 Crossbar Dial Telephone. Korn, Ferguson 244–54
Symmetrical Short Circuits on Saturated Alternators. Mikhail 1554–62
Synchronous Machine, Classification of the Reference Frames of a. Kron 720–7
Synchronous Machine Damping Torque at Low Speeds. Concordia 1550–3
Synchronous Machine Short Circuits, Analysis of. Cauburn, Gross ..... 671–8; disc. 678
Synchronous Machines and Their Application, Spring and Damping Coefficients of. Kilgore, Whitney ..... 226–9; disc. 229
Synchronous Machines, Per-Unit Inductances of. Kirschbaum 231–4
Synchronous Machines, Potier Reactance for Salient-Pole. Mikhail 235–8
Synthesis by Root Locus Method, Control System. Evans 66–9
Synthesizing Contactor Servomechanisms, A Frequency Response Method for Analyzing and. Kochenburger ..... 270–82; disc. 283
Synthetic Load for Testing Rectifiers. Tetherow 642–4
System, A Medium-Haul Carrier Telephone. Smith 1505–12
System, A Simplified 48-Channel Carrier Telephone. Erickson 1493–1500
System, Bus Transfer Tests on 2,300-Volt Station Auxiliary. Johnson, Thompson ..... 386–90; disc. 390
System, Crossbar Tandem. Collis 997–1004
System Design, Information Theory Applied to. Tuller 1612–14
System Disturbances, Automatic Control of Metal-Clad Switchgear Serving Oil Refinery Motors During Power. Horsfall, Thompson, Mills, Bobo ..... 1600–03; disc. 1603
System for a 4,500-Horsepower Gas-Turbine Electric Locomotive, Control. Warrick 508–13
System for Hydrogen-Cooled Generators, Continuous Scavenging. Snell, Grobel 1625–36
System for Short Submarine Cables, A Two-Channel Carrier Telegraph. Newell, Cramer 61–5
System for Telephone Lines of Short or Medium Length, An Improved Transmitted Carrier. Brodie 1501–04
System, Fundamentals of the Automatic Telephone Message Accounting. Mezzar ..... 255–68; disc. 269
System of Digital Recording and Telemetering, The Metrotype. Foster ..... 543–6; disc. 546
System of the Southern California Edison Company, Expansion of the. Kroneberg 861–4
System Performance with Motor-Driven Exciters, Excitation. Mellor, Temoshok 321–7
System Planning in the City of Los Angeles, Power. Williams, Kanouse ..... 900–07; disc. 907
System, Practical Experiences with Resonant Grounding in a Large 34.5-Kv. Brown, Gross ..... 1401–06; disc. 1406
System, Static Accuracy Performance of the Selsyn Generator Control Transformer. Kronacher ..... 645–53; disc. 653
System Synthesis by Root Locus Method, Control. Evans 66–9
System, The Number 5 Crossbar Dial Telephone Switching. Korn, Ferguson 244–54
System, Transient Analysis of a Voltage-Regulated Aircraft D-C. Scorgie 1318–23
Systems and Their Suppression, Some Aspects of Lightning Surges on Power. Kaneff 1544–9
Systems for Aircraft, Wide Speed Range A-C Electric. James, Judkins, Mershon ..... 1353–8; disc. 1358
Systems for 960 and 2,000 Megacycles, Microwave. Rector, Sutter ..... 1100–08; disc. 1108
Systems for Steel Mills, Basic Patterns for Arrangement of Electric Power. Finison ..... 54–9; disc. 59
Systems—Fundamentals and Basic Design Considerations, Underground Conduit for Electric Power. Watkins ..... 1582–90; disc. 1590
Systems, Measurement of Insulation Resistance on Energized. Brancato, McClinton 1238–42
Systems, Proposed Basic Impulse Insulation Levels for High-Voltage. Clem, Meador, Rudge, Powell ..... 953–60; disc. 960
Systems, The Determination and Allocation of the Capacity Benefits Resulting from Interconnecting Two or More Generating. Watchorn 1180–6
Systems, The Universal Director in Strowger Automatic Telephone. Ostline 1080–7
Systems with Compensation for Carrier Frequency Changes, Phase Lead for A-C Servo. Notthoff ..... 285–91; disc. 291

T

Tables, Basic Theory Underlying Bell System Facilities Capacity. Gracey ..... 238–43; disc. 243
Tachometer, A New High-Accuracy Counter-Type. Berry, Beattie ..... 686–90; disc. 690
Take-off, Automatic Feathering—To Reduce the Hazard of Aircraft Engine Failure at. Kershaw 1328–34
Tandem System, Crossbar. Collis 997–1004
Tandem Trunking in Los Angeles Metropolitan Area, Interexchange. Pfeiffer 1071–9
Tank Pressure with Transformer Loading in Sealed Transformers, Variations of. Tipton ..... 1669–73; disc. 1673

(Part I–1947)
Turbines for Power Generation, Control of Gas. Hoffmann, Mellor, Starkey.....1637–41; disc. 1641
Turbojet Thrust Instrumentation, Analogue Techniques for. Van Valkenburg, Matthews.....1342–6
Two-Channel Carrier Telegraph System for Short Submarine Cables, A. Newell, Cramer.....61–5
Type Servomechanisms, Integral Controller for Use in Carrier-. Cogriff.....1379–83

U

Unbalance on the Filtered Output Ripple of Polyphase Rectifiers, Effects of Supply Line. Hooper, McAdie.....766–70

Unbalanced Rotor Impedances, The Georges Phenomenon—Induction Motors with. Garbarino, Gross .....1569–74; disc. 1574
Underground Conduit for Electric Power Systems—Fundamentals and Basic Design Considerations. Watkins.....1582–90; disc. 1590
Underground Hydroelectric Power Plants. Gisiger 1169–75
Underground Hydroelectric Power Stations in Sweden. Ruck, Westerberg.....928–32
Underground Substation, A 5,000-Kva. Sinnott.....882–9; disc. 889
Units and Auxiliaries of the Consolidated Edison System, Thrust Bearing Problems and Their Solution on Turbine-Generator. Driscoll, Otten.....1642–7; disc. 1647
Units, Centralized Control Desirable for Single Boiler-Turbine-Generator. Lind, Geiger.....1176–9
Universal Director in Strowger Automatic Telephone Systems, The. Outline.....1080–7

V

Variable Speed Drive, Constant Frequency Alternator. Gould, Krupotich.....745–7; disc. 747
Variation Principle, An Improved Method of Measuring Dissipation Factor and Dielectric Constant Using the Susceptance. Miller, Whelan.....491–7
Variations of Tank Pressure with Transformer Loading in Sealed Transformers. Tipton.....1669–73; disc. 1673
Ventilation, An Experimental and Analytical Study of Turbine Generator Rotor. Fechheimer.....1563–9
Vibration and Fatigue Life of Steel Strand. Little, MacMillan, Majercak.....1473–8; disc. 1478
Vibration in the Field on a Large Single-Phase Frequency Changer, Investigation and Elimination of Unusual. Ballantyne, Allen, Baudry.....1264–72; disc. 1272
Vibration, Use of Techniques from Electrical Analogues in the Study of Transmission Line. Lummis, Klopfenstein.....1676–80
Video Television Networks, Local Wire. Nebel.....1451–60
Video Transmission, Clampers in. Dobs, Ricke.....477–87
Viewpoint, Aluminum Conductors from an Aircraft Manufacturer's. Schumacher.....1335–41
Voice Communication, Relaying, Telemetering, and Supervisory Control, Field Testing a Microwave Channel for. Pattison, Reagan, Leyland, Gunter.....945–51; disc. 951
Voltage Changes Produced by Single-Phase Loads, Effect of Three-Phase Motor Loads on. Faucett, Fisher, Helm.....1467–72
Voltage Gradient Meter, A. Tremaine, Check.....633–7; disc. 637
Voltage Measurement, The Irradiation of Spark Gaps for. Hardy, Craggs.....584–90
Voltage Power Fuse, A New High Interrupting Capacity Low-. Schuck.....770–6; disc. 776
Voltage Ratings for Transformers, Development of Preferred. St. Clair, Jalonack.....1049–59; disc. 1059
Voltage-Regulated Aircraft D-C System, Transient Analysis of a. Scorgie.....1318–23
Voltage Regulator on Steady-State Power Limit, Effect of Buck-Boost. Concordia.....380–4; disc. 384
Voltage Regulators, Dynamic Characteristics of Carbon Pile. Mills.....1347–52; disc. 1352
Voltage Regulators, Stability of. Bothwell.....1430–3; disc. 1433
Volts, Aircraft D-C Circuit Breakers for 28 and 120. Beall, Reifschneider.....1283–8

W

Wall, The Thermal Resistance Between Cables and a Surrounding Pipe or Duct. Buller, Neher.....342–7; disc. 347
Watt-Hour Meters, A New Device for Calibrating. Robison, Wickham.....732–4
Waves on Transmission Lines, Steady-State. Waidelich.....1521–4
Wheatstone Bridge, Resistance Wire Strain Gauges as Elements of the. Petruccelly.....742–4
Wheel-Slip and Wheel-Lock Protection, Locomotive. Smith.....1154–7
Wide Speed Range A-C Electric Systems for Aircraft. James, Judkins, Mershon.....1353–8; disc. 1358
Windings, Current in Equalizer Connections of D-C Machine Armature. Linville, Strang.....1219–26; disc. 1226
(Wire Communication) A Negative Impedance Repeater. Merrill.....1461–6
Wire Strain Gauges as Elements of the Wheatstone Bridge, Resistance. Petruccelly.....742–4
Wire Video Television Networks, Local. Nebel.....1451–60

Preface

The 1950 TRANSACTIONS (volume 69) of the American Institute of Electrical Engineers will be published in two parts.

Part I contains technical program papers and related discussions presented at the

Winter General Meeting, New York, N. Y., January 30–February 3, 1950.

Part II of the 1950 volume will contain approved papers and related discussions presented at the following meetings:

North Eastern District Meeting, Providence, R. I., April 26–28, 1950.
Great Lakes District Meeting, Jackson, Mich., May 11–12, 1950.
Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950.
Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950.
Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950.

Full correlation of all material in this volume has been accomplished by means of the multi-entry index beginning on page 664. Reference to any of the several subject entries for a technical paper will lead directly to the paper and to any published discussion on that paper.

The original number assigned each paper by the Technical Program Committee is given in the author index.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Part II of Volume 69 is expected to be available for distribution early in 1951.

Suggested Improvements in the Performance Calculations of Single-Phase Induction Motors

M. S. THACKER
FELLOW AIEE

H. V. GOPALAKRISHNA
NONMEMBER AIEE

THREE methods have been presented so far—the cross-field theory, the revolving-field theory and the system of symmetrical components—of calculating the performance of the split-phase and capacitor types of single-phase induction motors. In these analytical solutions either an arbitrary distribution of core-loss between the main and the cross-fields is suggested or the angle of hysteretic lag between the flux and the magnetomotive force is neglected and correction for core-loss made in the numerical calculations by treating it as if it were a friction loss. The subtraction of the total core-loss assumed constant at all loads from the rotor output is not justified theoretically though fair results are obtained ordinarily. It also is noticed that in the development of maximum torque equations the speed at which the maximum rotor input occurs is considered to be the same as the speed at which maximum power is developed and quite likely, safe results may not be obtained in all cases. In the present paper a complete and accurate analysis is provided for the solution of single-phase induction motor performance characteristics based on a paper by F. W. Suhr.[1]

Symbols and Factors

V_m = main phase rms volts
V_s = start phase rms volts
V_m^+ = positive sequence component of V_m
V_m^- = negative sequence component of V_m
V_s^+ = positive sequence component of V_s
V_s^- = negative sequence component of V_s
I_m = main phase rms amperes
I_s = start phase rms amperes
I_m^+ = positive sequence component of I_m
I_m^- = negative sequence component of I_m
I_s^+ = positive sequence component of I_s
I_s^- = negative sequence component of I_s
I_{2m}^+ = positive sequence component of M phase secondary current referred to primary current
I_{2m}^- = negative sequence component of M phase secondary current referred to primary current
I_{2s}^+ = positive sequence component of S phase secondary current referred to primary current
I_{2s}^- = negative sequence component of S phase secondary current referred to primary current
Z_m^+ = total positive sequence impedance of M phase
Z_m^- = total negative sequence impedance of M phase
Z_s^+ = total positive sequence impedance of S phase
Z_s^- = total negative sequence impedance of S phase
X_{1m} = reactance of M phase primary winding
R_{1m} = resistance of M phase primary winding

$$a = \frac{\text{effective conductors of } S \text{ phase}}{\text{effective conductors of } M \text{ phase}}$$

$$= a'\sqrt{\frac{X_s}{X_m}},\ a' \text{ being a constant}$$

a^2R_{1s} = primary resistance of S phase
a^2X_{1s} = primary leakage reactance of S phase
R_c = capacitor resistance
X_c = capacitor reactance
R_2 = equivalent M phase secondary resistance referred to primary winding
X_2 = equivalent M phase secondary reactance referred to primary winding
Z_2^{+1} = apparent secondary positive sequence impedance of M phase
Z_2^{-1} = apparent secondary negative sequence impedance of M phase
R_2^{+1} = apparent positive sequence M phase secondary resistance
X_2^{+1} = apparent positive sequence M phase secondary reactance
R_2^{-1} = apparent negative sequence M phase secondary resistance
X_2^{-1} = apparent negative sequence M phase secondary reactance
R_φ = resistance representing core loss when connected in series with X_φ

$$= \frac{\text{core loss}}{i_m^2}$$

X_φ = equivalent M phase mutual or magnetizing reactance
X = ideal short circuit reactance of motor ($R_2 = 0$)

$$= X_{1m} + X_2\frac{X_\varphi}{X_\varphi + X_2}$$

$X_0 = X_\varphi + X_{1m}$ = reactance of the primary winding with the secondary open circuited

$$K_\varphi = \sqrt{K_r} = \frac{X_\varphi}{X_0} = \sqrt{\frac{X_0 - X}{X_0}}$$

used only when $X_{1m} = X_2$

$i_m = \dfrac{V_m}{X_0}$ = primary current with the secondary open
T = internal torque developed in synchronous watts
= rotor input
P = power output in watts
$F + W$ = watts, friction, and windage
Pulley output $= P - (F + W)$
S = speed as a fraction of synchronism

$$s = \frac{\text{slip rpm}}{\text{synchronous rpm}} = 1 - \frac{\text{actual speed}}{\text{synchronous speed}} = 1 - S$$

Basic Assumptions

1. Squirrel cage rotor.
2. Sine wave distributions of the magnetomotive force and uniform air gap permeances.
3. Sinusoidal voltages and currents.
4. Space quadrature of main and start phases.
5. Same effective resistance of rotor at frequencies fs and $f(2-s)$.

Paper 50-1, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted August 23, 1948; made available for printing October 31, 1949.

M. S. THACKER and H. V. GOPALAKRISHNA are with the Indian Institute of Science, Bangalore, India.

Figure 1. Graphical representation of positive and negative sequence current components in a split-phase motor

Theory

Consider a stator having two windings M (main) and S (start) separated in space by 90 electrical degrees. Let I_m and I_s be the vectors representing the effective values of the currents $|I_m|$ and $|I_s|$ in the two windings. It is obvious that

$$|I_m| = a|I_s|$$

where

$$a = \frac{\text{effective conductors in } S \text{ phase}}{\text{effective conductors in } M \text{ phase}}$$

The currents I_m and I_s may be resolved into two balanced components of opposite phase order, Figures 1 and 2, such that

$$I_m = I_m^+ + I_m^- \tag{1}$$

$$I_s = I_s^+ + I_s^- \tag{2}$$

It is understood that all vectors are assumed to rotate in an anticlockwise direction in accordance with the standard convention. The sequence is determined not by any differences in direction of rotation but by the order in which the vectors pass any fixed position. I_m^+ is called as the positive sequence component and I_m^- as the negative sequence component. It is seen clearly that

$$I_s^+ = j\frac{I_m^+}{a} \tag{3}$$

$$I_s^- = -j\frac{I_m^-}{a} \tag{4}$$

Now equation 2 becomes

$$I_s = j\frac{I_m^+}{a} - j\frac{I_m^-}{a} \tag{5}$$

Operating on equation 5 by ja

$$jaI_s = -I_m^+ + I_m^- \tag{6}$$

and adding to equation 1 gives

$$I_m^- = \frac{I_m + jaI_s}{2} \tag{7}$$

Subtracting equation 6 from equation 1 results

$$I_m^+ = \frac{I_m - jaI_s}{2} \tag{8}$$

The equivalent circuits of the M phase of a single-phase induction motor having a primary impedance of $R_{1m}+jX_{1m}$ are shown in Figure 3(A). By combining the positive sequence secondary impedance, $R_2/s+jX_2$, with the magnetizing impedance, $R_\varphi+jX_\varphi$, of the positive sequence, equivalent circuit the apparent secondary impedance can be written as

$$Z_2^{+1} = \frac{1}{\dfrac{1}{\dfrac{R_2}{s}+jX_2} + \dfrac{1}{R_\varphi+jX_\varphi}} = R_2^{+1} + jX_2^{+1} \tag{9}$$

where the apparent secondary positive sequence resistance

$$R_2^{+1} = \left(\frac{R_2}{s}R_\varphi - X_2X_\varphi\right)\left(\frac{R_2}{s}+R_\varphi\right) + \frac{\left(\dfrac{R_2}{s}X_\varphi + X_2R_\varphi\right)(X_2+X_\varphi)}{\left(\dfrac{R_2}{s}+R_\varphi\right)^2 + (X_2+X_\varphi)^2} \tag{10}$$

and the apparent secondary positive sequence reactance

$$X_2^{+1} = \left(\frac{R_2}{s}X_\varphi + X_2R_\varphi\right)\left(\frac{R_2}{s}+R_\varphi\right) - \frac{\left(\dfrac{R_2}{s}R_\varphi - X_2X_\varphi\right)(X_2+X_\varphi)}{\left(\dfrac{R_2}{s}+R_\varphi\right)^2 + (X_2+X_\varphi)^2} \tag{11}$$

By combining the negative sequence secondary impedance

$$\frac{R_2}{2-s} + jX_2$$

with the magnetizing impedance, $R_\varphi+jX_\varphi$, of the negative sequence equivalent circuit the apparent secondary negative sequence can be written as

$$Z_2^{-1} = \frac{1}{\dfrac{1}{\dfrac{R_2}{2-s}+jX_2} + \dfrac{1}{R_\varphi+jX_\varphi}} = R_2^{-1} + jX_2^{-1} \tag{12}$$

Figure 2. Graphical representation of positive and negative sequence current components in a capacitor motor

where the apparent secondary negative sequence resistance

$$R_2^{-1} = \left(\frac{R_2}{2-s}R_\varphi - X_2X_\varphi\right)\left(\frac{R_2}{2-s}+R_\varphi\right) + \frac{\left(\dfrac{R_2}{2-s}X_\varphi + X_2R_\varphi\right)(X_2+X_\varphi)}{\left(\dfrac{R_2}{2-s}+R_\varphi\right)^2 + (X_2+X_\varphi)^2} \tag{13}$$

and the apparent secondary negative sequence reactance

$$X_2^{-1} = \left(\frac{R_2}{2-s}X_\varphi + X_2R_\varphi\right)\left(\frac{R_2}{2-s}+R_\varphi\right) - \frac{\left(\dfrac{R_2}{2-s}R_\varphi - X_2X_\varphi\right)(X_2+X_\varphi)}{\left(\dfrac{R_2}{2-s}+R_\varphi\right)^2 + (X_2+X_\varphi)^2} \tag{14}$$

so that, the total positive sequence impedance of M phase

$$Z_m^+ = (R_{1m} + R_2^{+1}) + j(X_{1m} + X_2^{+1}) \tag{15}$$

and the total negative sequence impedance of M phase

$$Z_m^- = (R_{1m} + R_2^{-1}) + j(X_{1m} + X_2^{-1}) \tag{16}$$

The single-phase equivalent circuits for the S phase are shown in Figure 3(B). In the equivalent circuits the primary impedance, $a^2R_{1s}+ja^2X_{1s}$, is in series with an external impedance. The rotor quantities previously referred to the M phase will have to be multiplied now by the square of the transformation ratio. The apparent secondary impedance of the S phase, therefore, differs from the M phase by a^2. Hence, in the general case of a capac-

itor motor the total positive sequence impedance of S phase

$$Z_s^+=(R_s+a^2R_{1s}+a^2R_2^{+1})+j(-X_s+a^2X_{1s}+a^2X_2^{+1}) \quad (17)$$

and the total negative sequence impedance of S phase

$$Z_s^-=(R_s+a^2R_{1s}+a^2R_2^{-1})+j(-X_s+a^2X_{1s}+a^2X_2^{-1}) \quad (18)$$

The voltages V_m and V_s applied across the phases M and S respectively may be resolved into two balanced components of opposite phase order. When both positive and negative sequence voltages are applied simultaneously, the currents of the two sequences do not react upon each other; they may be computed separately. Thus

$$V_m=V_m^++V_m^-=I_m^+Z_m^++I_m^-Z_m^- \quad (19)$$

$$V_s=V_s^++V_s^-=I_s^+Z_s^++I_s^-Z_s^- \quad (20)$$

In single-phase motors the same voltage is impressed across both M and S phases, that is, $V_s \equiv V_m$. The resolution of the impressed voltage across M and S phases into positive and negative sequence components is illustrated in Figures 4 and 5. Equation 20 becomes

$$V_m=I_s^+Z_s^++I_s^-Z_s^- \quad (21)$$

From equations 3 and 4 this is

$$V_m=j\frac{I_m^+}{a}Z_s^+-j\frac{I_m^-}{a}Z_s^- \quad (22)$$

The positive and negative sequence currents of the main winding are determined from equations 19 and 22, so that

$$I_m^+=V_m\left[\frac{Z_s^--jaZ_m^-}{Z_m^+Z_s^-+Z_m^-Z_s^+}\right] \quad (23)$$

$$I_m^-=V_m\left[\frac{Z_s^++jaZ_m^+}{Z_m^+Z_s^-+Z_m^-Z_s^+}\right] \quad (24)$$

The main phase current being the vector sum of $I+_m{}^+$ and $I_m{}^-$ is

$$I_m=V_m\left[\frac{(Z_s^++Z_s^-)+ja(Z_m^+-Z_m^-)}{Z_m^+Z_s^-+Z_m^-Z_s^+}\right] \quad (25)$$

The start phase current computed from equations 23, 24, and 5 is

$$I_s=V_m\left[\frac{(Z_m^++Z_m^-)+j\left(\frac{Z_s^-}{a}-\frac{Z_s^+}{a}\right)}{Z_m^+Z_s^-+Z_m^-Z_s^+}\right] \quad (26)$$

By Figure 6 and equations 25 and 26, the line current

$$I_L=I_m+I_s$$

$$=V_m\frac{(Z_m^++Z_m^-+Z_s^++Z_s^-)+j\left(aZ_m^+-aZ_m^-+\frac{Z_s^-}{a}-\frac{Z_s^+}{a}\right)}{Z_m^+Z_s^-+Z_m^-Z_s^+}$$

$$=p-jq \quad (27)$$

The power factor is given by

$$\frac{p}{\sqrt{p^2+q^2}}$$

The application of Kirchoff's laws to the loops of the equivalent circuits in Figure 3(A) will give the relationship between the secondary currents and the component currents of the main phase current. Thus

$$I_{2m}^+=\frac{R_\varphi+jX_\varphi}{\left(\frac{R_2}{s}+jX_2\right)+(R_\varphi+jX_\varphi)}I_m^+ \quad (28)$$

and

$$I_{2m}^-=\frac{R_\varphi+jX_\varphi}{\left(\frac{R_2}{2-s}+jX_2\right)+(R_\varphi+jX_\varphi)}I_m^- \quad (29)$$

It is true that

$$|I_{2s}^+|=\left|\frac{I_{2m}^+}{a}\right| \quad (30)$$

$$|I_{2s}^-|=\left|\frac{I_{2m}^-}{a}\right| \quad (31)$$

Since the phase orders of the positive-sequence and negative-sequence currents are opposite, the torques due to these currents are opposite. Therefore the total internal torque is

$$T=T^+-T^-$$

$$=|I_{2m}^+|^2\frac{R_2}{s}+|I_{2s}^+|^2a^2\frac{R_2}{s}-|I_{2m}^-|^2\frac{R_2}{2-s}-|I_{2s}|^2a^2\frac{R_2}{2-s} \quad (32)$$

Now, from equations 28 and 29 it is clear that

$$|I_{2m}^+|^2\frac{R_2}{s}=\frac{R_\varphi^2+X_\varphi^2}{\left(\frac{R_2}{s}+R_\varphi\right)^2+(X_2+X_\varphi)^2}|I_m^+|^2\frac{R_2}{s} \quad (33)$$

and

$$|I_{2m}^-|^2\frac{R_2}{2-s}=\frac{R_\varphi^2+X_\varphi^2}{\left(\frac{R_2}{2-s}+R_\varphi\right)^2+(X_2+X_\varphi)^2}|I_m^-|^2\frac{R_2}{2-s} \quad (34)$$

Equations 33 and 34 in conjunction with equations 30 and 31 give

$$T=2\left[\frac{R_\varphi^2+X_\varphi^2}{\left(\frac{R_2}{s}+R_\varphi\right)^2+(X_2+X_\varphi)^2}|I_m^+|^2\frac{R_2}{s}-\frac{R_\varphi^2+X_\varphi^2}{\left(\frac{R_2}{2-s}+R_\varphi\right)^2+(X_2+X_\varphi)^2}|I_m^-|^2\frac{R_2}{2-s}\right] \quad (35)$$

synchronous watts

The power output is

$$P=T(1-s) \text{ watts} \quad (36)$$

Subtracting the friction and windage losses yields

$$\text{Pulley output}=T(1-s)-(F+W) \text{ watts} \quad (37)$$

$$\text{Pulley output}=\frac{112.7}{\text{synchronous rpm}}[T(1-s)-(F+W)] \text{ ounce-feet} \quad (38)$$

$$\text{Efficiency}=\frac{T(1-s)-(F+W)}{|V_mp|} \quad (39)$$

Figure 3. Equivalent circuits of a single-phase induction motor

External impedance: for capacitor motor $=R_c-jX_c$; for split-phase motor $=0$

With the quadrature circuit open under running conditions as in capacitor start and split-phase motors: $I_m^+=I_m^-$ and $I_s^+=-I_s^-$

The value of the resistance R_φ representing the core loss included in the equivalent circuits is

$$R_\varphi = \frac{\text{Core loss}}{i_m^2} = \frac{\text{Core loss}}{\left[\dfrac{V_m}{X_\varphi + X_{1m}}\right]^2} \tag{40}$$

The foregoing equations are directly applicable to capacitor motors. An example is worked out in Appendix I.

The split-phase and capacitor-start motors will have the auxiliary winding disconnected when running so that

$$I_s = 0 \tag{41}$$

From equation 2

$$I_s^+ = -I_s^- \tag{42}$$

And from equations 7 and 8

$$I_m^+ = \frac{I_m}{2} = I_m^- \tag{43}$$

These conditions are illustrated in Figure 3 and by the vector diagram of Figure 7. Equation 19 expressing the relation between the applied voltage and the currents flowing for a given slip reduces to

$$\begin{aligned} V_m &= I_m^+(Z_m^+ + Z_m^-) \\ &= I_m^+[(R_{1m} + R_2^{+1}) + j(X_{1m} + X_2^{+1}) + \\ &\qquad (R_{1m} + R_2^{-1}) + j(X_{1m} + X_2^{-1})] \\ &= 2I_m^+\left[\left(R_{1m} + \frac{R_2^{+1} + R_2^{-1}}{2}\right) + \right. \\ &\qquad \left. j\left(X_{1m} + \frac{X_2^{+1} + X_2^{-1}}{2}\right)\right] \end{aligned} \tag{44}$$

Therefore

$$|I_m^+| = \frac{\dfrac{V_m}{2}}{\sqrt{\left(R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}\right)^2 + \left(X_{1m} + \dfrac{X_2^{+1} + X_2^{-1}}{2}\right)^2}} = |I_m^-| \tag{45}$$

The internal torque expressed by the equation 35 gets modified to

$$T = 2R_2(R_\varphi^2 + X_\varphi^2)|I_m^+|^2 \times \left[\frac{1}{\left\{\left(\dfrac{R_2}{s} + R_\varphi\right)^2 + (X_2 + X_\varphi)^2\right\}s} - \frac{1}{\left\{\left(\dfrac{R_2}{2-s} + R_\varphi\right)^2 + (X_2 + X_\varphi)^2\right\}(2-s)}\right] \text{ synchronous watts} \tag{46}$$

and is equal to the power input to the rotor.

The power output

$$P = T(1-s) \text{ watts} \tag{47}$$

$$\text{Pulley output} = T(1-s) - (F + W) \text{ watts} \tag{48}$$

$$= \frac{112.7}{\text{synchronous rpm}} \times [T(1-s) - (F + W)] \text{ ounce-feet} \tag{49}$$

As the starting winding is disconnected the line current = main phase current = $2I_m^+$, so that

$$|I_L| = \frac{V_m}{\sqrt{\left(R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}\right)^2 + \left(X_{1m} + \dfrac{X_2^{+1} + X_2^{-1}}{2}\right)^2}} \tag{50}$$

The power factor is

$$\frac{R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}}{\sqrt{\left(R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}\right)^2 + \left(X_{1m} + \dfrac{X_2^{+1} + X_2^{-1}}{2}\right)^2}} \tag{51}$$

The input is the product of the impressed voltage and the in-phase component of the line current, found by multiplying equations 50 and 51. Thus

$$\text{Input} = \frac{V_m^2\left(R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}\right)}{\left(R_{1m} + \dfrac{R_2^{+1} + R_2^{-1}}{2}\right)^2 + \left(X_{1m} + \dfrac{X_2^{+1} + X_2^{-1}}{2}\right)^2} \tag{52}$$

$$\text{Efficiency} = \frac{\text{Pulley output (equation 48)}}{\text{Input (equation 52)}} \tag{53}$$

A sample calculation is shown in Appendix II.

The speed at which maximum internal torque is developed by the motor now will be determined. Now from equation 32

$$T = 2\left[|I_{2m}^+|^2 \frac{R_2}{s} - |I_{2m}^-|^2 \frac{R_2}{2-s}\right]$$

In Appendix III, it is shown that this expression assumes the form

$$T = \frac{4V_m^2 R_2(\chi S^3 + \omega S)}{\gamma S^4 + \mu S^2 + \epsilon} \tag{54}$$

where χ, ω, γ, μ and ϵ could be computed from the motor constants. If the core-loss, R_φ, is neglected this expression is identical with the equation given by West[6] who derived his expression by the cross field theory. On differentiation,

$$\frac{dT}{dS} = 4V_m^2 R_2 \times \frac{S^4(-\gamma\chi) + S^2(\mu\chi - 3\gamma\omega) + S^2(3\chi\epsilon - \mu\omega) + \epsilon\omega}{(\gamma S^4 + \mu S^2 + \epsilon)^2}$$

The speed corresponding to maximum internal torque is obtained by equating the numerator to zero.

That is,

$$S^4(-\gamma\chi) + S^2(\mu\chi - 3\gamma\omega) + S^2(3\chi\epsilon - \mu\omega) + \epsilon\omega = 0 \tag{55}$$

As only even powers of S exist the equation is of the third degree in S^2 which can be solved easily.

The power output is given by

$$P = TS = 4V_m^2 R_2 \frac{(\chi S^4 + \omega S^2)}{\gamma S^4 + \mu S^2 + \epsilon} \tag{56}$$

Differentiating

$$\frac{dP}{dS} = 8V_m^2 R_2 S \frac{(\mu\chi - \gamma\omega)S^4 + 2\chi\epsilon S^2 + \omega\epsilon}{(\gamma S^4 + \mu S^2 + \epsilon)^2}$$

$S = 0$ indicates that the power output is zero at standstill. The biquadratic expression in the numerator, equated to zero gives the speed for maximum power output.

That is

$$(\mu\chi - \gamma\omega)S^4 + 2\chi\epsilon S^2 + \omega\epsilon = 0 \tag{57}$$

The maximum or breakdown power output is calculated easily. This is shown in Appendix IV.

Appendix I

These are the running performance calculations on a capacitor start and run motor for the same motor for which constants are given in Morrill's paper[13] with some additional items as given by Puchstein and Lloyd[8]. The values for this 4-pole 1/4-horsepower 110-volt motor are

$R_{1m} = 2.02$; $a^2R_{1s} = 1.18^2 \times 5.12 = 7.13$; $R_2 = 4.12$; R_e (at start) $= 3$; X_e (at start) $= 14.5$; R_e (running) $= 9$; X_e (running) $= 172.0$; $X_{1m} = 2.79$; $a^2X_{1s} = 1.18^2 \times 2.31 = 3.22$; $X_2 = 2.12$; $a = 1.18$; $a^2 = 1.39$; $X_m = 66.8$; $s = 0.04$. Friction and windage $= 13$ watts; Iron losses $= 24$ watts.

Calculations

$X_0 = 66.8 + 2.79 = 69.59$; $i_m = \dfrac{110}{69.59} = 1.58$;

$R_\varphi = \dfrac{6624}{1.58^2} = 9.6$; $R_2^{+1} = 32.76$;

$X_2^{+1} = 41.23$; $R_2^{-1} = 1.97$; $Z_m^+ = 34.78 + j44.02$; $Z_m^- = 3.99 + j4.89$; $Z_s^+ = 61.67 - j111.47$; $Z_s^- = 18.87 - j165.86$;

$$I_m^- = 110\frac{9.73 - j70.43}{8748.61 - j5081.15}$$

$$I_m^+ = 110\frac{24.64 - j170.57}{8748.61 - j5081.15}$$

$$I_m = I_m^+ + I_m^- = 1.64 - j2.08 = 2.65/-51°47'$$

Figure 4 (left). Graphical representation of positive and negative sequence voltage components in a split-phase motor

Figure 5 (right). Graphical representation of positive and negative sequence voltage components in a capacitor motor

$$I_s = \frac{j}{a}(I_m^+ - I_m^-) = 0.729 + j0.582$$
$$= 0.933\angle 38°36'$$

$$|I_m^+|^2 = 110^2 \times 0.00029$$
$$|I_m^-|^2 = 110^2 \times 0.00005$$

$T = 186.8$ synchronous watts
Pulley putput $= 186.8\,(1-0.04) - 13$
$= 166$ watts

Appendix II

Machine data are taken from the example given by Puchstein and Lloyd[4] for a single-phase induction motor, 1/6 horsepower, 110 volts, 6 poles, 60 cycles. In the symbols of this paper

$R_{1m} = 3.95$; $R_3 = 3.7$; $X = 9.72$; $K_r = 0.862$; $(F+W) = 9$ watts

Performance Calculations

$$K_r = \frac{X_0 - X}{X_0}$$

Therefore

$X_0 = 70.4$; $X_\varphi = \sqrt{K_r X_0} = 65.35$; $X_{1m} = X_3 = 5.05$; $i_m = 1.565$; $R_\varphi = 12$; $R_3^{+1} = 32.1$; $R_3^{-1} = 1.40$; $X_3^{+1} = 39.30$; $X_3^{-1} = 4.70$.

Substituting in equation 46

$T = 123.93$ synchronous watts
Pulley output $= 123.93 \times 0.97 - 9 = 111.2$ watts.

From equation 50 $|I_L| = 3.23$; from equation 51 $\cos\varphi = 0.61$; and from equation 53 efficiency $= 0.514$.

Appendix III

This demonstrates the calculation of the total internal torque of a capacitor-start or split-phase motor.

Equation 32 can be put down as a function of S thus

$$T = 2[\varphi(S) - \varphi(-S)] \text{ where } S = 1 - s$$

$$\varphi(S) = |I_{3m}^+|^2 \frac{R_3}{1-S}$$
$$= \left| I_m + \frac{R_3^{+1} + jX_3^{+1}}{\frac{R_3}{1-S} + jX_3} \right|^2 \frac{R_3}{1-S}$$
$$= \left| \frac{V_m}{Z_m^+ + Z_m^-} \frac{R_3^{+1} + jX_3^{+1}}{\frac{R_3}{1-S} + jX_3} \right|^2 \frac{R_3}{1-S}$$
$$= \left| \frac{V_m}{(2R_{1m} + 2jX_{1m} + R_3^{+1} + jX_3^{+1} + R_3^{-1} + jX_3^{-1})} \times \frac{R_3^{+1} + jX_3^{+1}}{\frac{R_3}{1-S} + jX_3} \right|^2 \frac{R_3}{1-S}$$
$$= \left| \frac{V_m}{2R_{1m} + 2jX_{1m} + \frac{1}{\frac{1}{\frac{R_3}{1-S} + jX_3} + \frac{1}{R_\varphi + jX_\varphi}} + \frac{1}{\frac{1}{\frac{R_3}{1+S} + jX_3} + \frac{1}{R_\varphi + jX_\varphi}}} \times \frac{\frac{1}{\frac{1}{\frac{R_3}{1-S} + jX_3} + \frac{1}{R_\varphi + jX_\varphi}}}{\frac{R_3}{1-S} + jX_3} \right|^2 \frac{R_3}{1-S}$$
$$= \left| \frac{V_m(D + CS)B}{AD^2 + 2BED - S^2F} \right|^2 R_3(1-S)$$

where

$A = 2R_{1m} + 2jX_{1m}$
$B = R_\varphi + jX_\varphi$
$C = R_\varphi + jX_\varphi + jX_3$
$D = R_\varphi + jX_\varphi + jX_3 + R_3$
$E = R_3 + jX_3$
$F = AC^2 + 2jBCX_3$

Grouping real and imaginary components yields

$$V_m^2 R_3 \left| \frac{(Se_1 + f_1) + j(Sg_1 + h_1)}{(S^2a_1 + b_1) + j(S^3c_1 + d_1)} \right|^2 (1-S)$$

where

$a_1 = 2R_{1m}[(X_3 + X_\varphi)^2 - R_\varphi^2] + 4R_\varphi X_{1m}(X_3 + X_\varphi) + 2X_3R_\varphi \times (X_3 + 2X_\varphi)$

$b_1 = 2R_{1m}[(R_3 + R_\varphi)^2 - (X_3 + X_\varphi)^2] - 4X_{1m}(R_3 + R_\varphi)(X_3 + X_\varphi) + 2R_\varphi(R_3^2 - X_3^2 - 2X_3X_\varphi) + 2R_3(R_\varphi^2 - X_\varphi^2 - 2X_3X_\varphi)$

$c_1 = (2X_3X_\varphi - 4R_{1m}R_\varphi)(X_3 + X_\varphi) - 2R_\varphi^2(X_{1m} + X_3) + 2X_{1m}(X_3 + X_\varphi)^2$

$d_1 = 2X_{1m}[(R_3 + R_\varphi)^2 - (X_3 + X_\varphi)^2] + 4R_{1m}(R_3 + R_\varphi)(X_3 + X_\varphi) + 2X_\varphi(R_3^2 - X_3^2 - X_3X_\varphi) + 4R_3R_\varphi(X_3 + X_\varphi) + X_3R_\varphi^2$

$e_1 = R_\varphi^2 - X_\varphi^2 - X_3X_\varphi$
$f_1 = R_\varphi^2 + R_3R_\varphi - X_\varphi^2 - X_3X_\varphi$

Table I. Calculating the Performance of Capacitor Start and Run Motor

Motor Running With a Slip of 4 Per Cent

Method	I_m	I_s	Net Output
Double revolving field (Morrill)	$2.47\angle -59°3'$	$0.948\angle 38°45'$	177 watts

Figure 6. Vector relationships in a capacitor motor

$$g_1 = 2X_\varphi R_\varphi + X_2 R_\varphi$$
$$h_1 = 2X_\varphi R_\varphi + X_2 R_\varphi + R_2 X_\varphi$$

The expression may be written down in the form

$$V_m^2 R_3 \left[\frac{(Se_1+f_1)^2+(Sg_1+h_1)^2}{(S^2a_1+b_1)^2+(S^2c_1+d_1)^2} \right](1-S)$$

$$= \frac{V_m^2 R_3 [S^3(-c_1^2-g_1^2)+ S^2(c_1^2+g_1^2-2e_1f_1-2g_1h_1)+ S(2e_1f_1+2g_1h_1-f_1^2-h_1^2)+f_1^2+h_1^2]}{S^4(a_1^2+c_1^2)+S^3(2a_1b_1+2c_1d_1)+ b_1^2+d_1^2}$$

Finally the expression assumes the form

$$\varphi(S) = V_m^2 R_2 \frac{\chi S^3+\psi S^2+\omega S+\eta}{\gamma S^4+\mu S^3+\epsilon}$$

and

$$\varphi(-S) = V_m^2 R_2 \frac{-\chi S^3+\psi S^2-\omega S+\eta}{\gamma S^4+\mu S^3+\epsilon}$$

where

$$\chi = -c_1^2-g_1^2$$
$$\psi = c_1^2+g_1^2-2e_1f_1-2g_1h_1$$
$$\omega = 2e_1f_1+2g_1h_1-f_1^2-h_1^2$$
$$\eta = f_1^2+h_1^2$$
$$\gamma = a_1^2+c_1^2$$
$$\mu = 2a_1b_1+2c_1d_1$$
$$\epsilon = b_1^2+d_1^2.$$

This gives

$$T = \frac{4V_m^2 R_2[\chi S^3+\omega S]}{\gamma S^4+\mu S^3+\epsilon}$$

Appendix IV

This is an example of maximum rotor input and maximum power output calculations. Machine data are taken from the example by Veinott[7] for a single-phase induction motor, 110 volts, 4 poles, 60 cycles. In the notations of this paper

$R_{1m}=3.8$; $R_3=4.65$; $X_\varphi=X_\psi+X_{1m}=110$; $X=X_{1m}+K_pX_2=8.3$; $K_p=0.964$; $X_{1m}=X_2$ (assumption); Core loss $=19$ watts; Friction and windage $=10$ watts.

Then

$X_{1m}=X_1=4.23$; $X_\varphi=105.77$; $i_m=1$; $R_\varphi=19$.

By Appendix III,

$e_1=-11{,}273$; $g_1=4{,}100$; $a_1=15{,}962$; $c_1=162{,}918$; $f_1=-11{,}185$; $h_1=4{,}501$; $b_1=-274{,}576$; $d_1=-113{,}078$.

so that

$\chi=-0.1439\times10^9$; $\omega=0.1436\times10^9$; $\gamma=51.9\times10^4$; $\mu=-124.3\times10^9$; $\epsilon=88.18\times10^9$.

Equation 55 gives

$$0.519S^3-0.317S^2-1.406S^2+0.8818=0$$

which on solving yields

$$S=0.794$$

Therefore

$T=310$ watts

From equation 57

$$0.1043S^4-0.2538S^3+0.1266=0$$

resulting in $S=0.8367$ as against 0.81 given by Veinott[7] and 0.817 given by Puchstein and Lloyd.[6] From equation 56 $P=253.5$. The net mechanical power at the rotor shaft (253.5 watts) minus watts due to friction and windage $=243.5$ as against 242 watts of Veinott's result.

Discussion

F. W. Suhr (General Electric Company, Fort Wayne, Ind.): In the first half of this paper the authors have closely followed the earlier work of this discusser. They have introduced the innovation of including the core loss as an equivalent resistance (R_φ) in series with the magnetizing reactance (X_φ). To the practical motor designer this refinement does not seem to be justified for these reasons:

1. Core loss is (in part at least) a loss subtractive from rotor output.

2. Harmonic torques and load losses (which are not too well known) cause a

greater error than would result from this refinement in calculation technique.

3. It is doubtful that testing techniques are sufficiently accurate to distinguish the difference in rotor output or stator input whether based on the concept of totally subtractive core loss or the method proposed by the authors.

4. Much greater errors in calculation result from the assumption that the motor "constants" are really constant since: R_1 is a function of the rotor cage frequencies; the exact winding temperatures at the test load are rarely known, thus R_1 and R_2 are not exact; X_1 and X_2 are functions of leakage flux density and thus vary appreciably from no load to breakdown; X_ϕ increases as the speed decreases under load because of increasing primary voltage drop. This is due to desaturation of the main flux paths.

Solution of the maximum theoretical internal torque and power output in terms of speed, as given by the authors' equations 55 and 56 respectively, does not appear to be of real practical value for these reasons;

1. In their collapsed or "short hand" forms they appear to be fairly simple. But a great deal of calculation labor is involved in working out the derived "constants" $\gamma, X_1, \mu, a, \omega$. While an arithmetic solution of a cubic equation is possible, it can hardly be called "easy."

Even a designer of only very limited experience will soon learn at what value of slip he can expect maximum torque to occur. By making about three assumptions as to the value of slip in the breakdown region he can calculate the torques and by plotting torque against slip (or speed) he can arrive at the proper value. This is a very simple calculation which would consume only a fraction of the time that would be required to perform the operations called for by the authors' equations. Many designers have semiempirical formulas for break-down torque which are quite simple.

2. The same reasons given previously for not using the R_ϕ apply equally well here.

While I have not checked all of the algebraic manipulations involved in deriving the authors' equations 55 and 56, I do not doubt their mathematical precision for the assumed conditions. When rotor resistance for the low-frequency forward field differs from rotor resistance for the high-frequency backward field or when X_1, X_2, and X_ϕ vary with the amount of current drawn by the motor, then the assumptions are no longer valid. The simpler, but less elegant, method of assuming the slip and then applying resistance and reactance values that obtain at this condition will yield more accurate results.

Edward Bretch (Century Electric Company, St. Louis, Mo.): In the January 1950 issue of Electrical Engineering,[1] the following observation is noted: "When a comprehensive practical engineering problem must be solved, however, the first, and perhaps the most important task is to make the necessary and proper assumptions to reduce the complexity of the problem to make its solution possible."

The subject of single-phase squirrel-cage motor theory has been and still is a confused subject, due to the early assumptions on which the pioneer theories were based. Thacker and Gopalakrishna mention the rotating-field and cross-flux theories, each based on different assumptions, which theories are not altogether consistent with each other or with actual test results. It appears that 50 or 60 years ago when the "necessary and proper assumptions to reduce the complexity of the problem to make its solution possible" were made, there was not sufficient basic knowledge from which to develop consistent assumptions. These pioneer theories appear to have been accepted without regard to the correctness of the assumptions on which they were based. While the mathematics applied to them have kept pace with the times, no attention has been given to exploring and correcting the assumption on which they are based.

B. G. Lamme[2] did make an exploration into the physics of the rotating field theory and sums up as follows: "Such a set or unit has certain characteristics which are so similar to those of the usual single-phase motor that on first consideration one would assume them to be identical. However, a more careful study of the individual operating conditions shows that the similarity is a general one and a number of decided discrepancies are found." On the other hand, no test has so far been cited which verifies the basic assumption of the rotating field theory, namely that two equal constant fluxes rotating at equal speed in opposite directions combine vectorially into a single-phase alternating flux.

While Mr. Suhr may have improved on the mathematics applied to the problem by the use of symmetrical components, it seems that his method is still fundamentally based on the same assumption which Mr. Lamme found by actual test to be inconsistent.

As to the cross-flux assumptions, this theory assumes that the cross flux varies directly with rotor speed, equals the main flux at synchronism, and continues to increase directly with rotor speed above synchronism. At one time the writer addressed the late Dr. A. S. McAllister who was an outstanding advocate of the cross-flux theory, inquiring as to how this increased cross flux above synchronism could be tested and verified. He suggested that the rotor of a single-phase motor be driven above synchronism and the cross flux measured by voltage induced in a second stator winding placed in space quadrature with the main stator winding. However, this test shows that while the cross flux is approximately equal to the main flux at synchronism, it is not proportional to rotor speed but more nearly inversely proportional to slip, since it decreases as slip increased both above and below synchronism. When Dr. McAllister was shown these results he expressed surprise but had no explanation for the discrepancy between the theory and test results.

Steinmetz,[3] some years after the rotating field and cross flux theories were established, proposed another theory which appears to be more logical and to represent more accurately than the pioneer theories the actual actions within the single-phase squirrel-cage motor. This, briefly, is his theory: "In a single-phase motor, one of the two superimposed quadrature fields is excited by the primary current and the other by the secondary currents carried into the quadrature position by the rotation of the secondary." While, so far as known, he never developed this theory in detail, it appears to be well worth exploring. Likewise, it is felt that the basic assumptions on which the pioneer single-phase theories were based should also be given some further attention. In solving engineering problems, correct assumptions are just as important as correct mathematics.

M. S. Thacker and H. V. Gopalakrishna: Mr. Suhr's comments are correct. There are many other limitations in the analysis. Admittedly, the ultimate design method is the one which takes into account all of the variables, but provision for all the variables in the equations results in the most complicated formulae. From the practical point of view, there is a large measure of evidence to show that the average values assumed for the less important so-called constants will yield the operating characteristics which are in substantial agreement with the test results. The paper was presented with a view to giving a clear concept of the inter-relationships in the motor and to develop the desired degree of accuracy in the equations which form the basis of our other paper.[1]

The comments of Mr. Bretch in trying to overthrow the principal theories are based on misinterpretation of experimental observation and theoretical deductions. Mr. Puchstein, in his letter to the editor, has very ably thrashed out all the issues raised in the discussion.[2] Experimental results do affirm that a nonrotating field is present in the air gap when two oppositely-rotating fluxes are produced by two equal 3-phase windings placed in the same slots but connected in series. Theory also proves that the cross-field will be in direct proportion to the speed only if the main flux is constant. The figures in Table II of the letter[2] afford conclusive proof that the voltage induced in the starting winding plotted against speed has the same shape as predicted by the theory. The pioneer theories have withstood the test of time and practice. Although new investigations are essential to progress, there is hardly any basis for associating the scheme visualized by Steinmetz and so far not translated into concrete process with our method of analyzing the performance of the single-phase induction motor.

Electric Fences—Their Hazards, Types, Regulations, and Safe Application

CHARLES F. DALZIEL
MEMBER AIEE

SUSTAINED purchases of 400,000 electric fence controllers per year by American farmers substantiate the fact that the electric fence is a practical and valuable aid to modern farming. These devices have been accepted, not only in this country but also in foreign countries, including Australia, Canada, and the countries of Europe. That this general acceptance is substantial is evident from Danish estimates that the number of electric fence controllers now in use exceeds 100,000; the number of farms in Denmark is approximately 210,000.

Since the primary objective of the electric fence is to control farm animals by subjecting them to a powerful shock when they contact the fence wire, human beings will be similarly affected, and attention must be given to controlling the shock intensity so that it will be harmless to both man and beast. This objective has been achieved in approved* electric fence controllers. Approved electric fence controllers are safe, effective, and economical. They are the result of over ten years' experience in the field and in the laboratory.

The electric fence consists of one or more bare wires, such as ordinary galvanized wire or barbed wire, insulated from ground, which are energized from a device called a controller. An animal or human touching the wire completes the circuit to ground thereby receiving a painful but harmless shock. The wire is strung on insulators supported by lightweight poles at a vertical distance about three-quarters of the height of the animal. Where animals of different sizes are to be controlled in the same enclosure, two or more wires, placed at different levels, are used. In cases where poor grounding conditions predominate, such as in sandy or very dry soil, effectiveness can be improved by installing a ground wire about six inches from the ungrounded energized wire or wires.

The idea of utilizing electric shock as a means of controlling animals appeals to the imagination. Application appears so simple that many laymen have constructed homemade devices with disastrous results. Much concern has been given to effectiveness by these laymen and far too little concern has been given to electric shock hazards. Novices, such as radio amateurs, garage mechanics, and ambitious farmers, have resorted to various schemes, by far the most dangerous being the use of the ungrounded side of the 120-volt lighting circuit protected only by fuses or by $7^1/_2$ to 100 watt electric lamps. Such means may give fair results during ordinary conditions, poor results during conditions of high grounding resistance, and numerous fatalities to both humans and animals during good grounding conditions. Other dangerous homemade gadgets currently in use involve radio transformers and neon sign transformers. Fatalities are of serious concern. Lack of effectiveness of these homemade devices has done much to discourage the use of electric fences in general. These unfortunate instances have done much to discourage both scientific development and application. The homemade gadget has given the electric fence its bad reputation as an executioner of humans and animals. Estimates place the yearly toll between 10 to 15 humans, while animal fatalities are said to be in the hundreds. In contrast to the continuing number of fatalities caused by unauthorized devices, the approved electric fence controller continues to maintain an almost zero fatality record.

The electrical profession, alert to new and useful applications of electricity, is much concerned over the continuing number of fatalities resulting from nonapproved fences. The continuing number of serious accidents is of special importance in connection with present efforts to complete the electrification of all farms in the country. This expansion must be accompanied with sound technical advice and adequate supervision up to the point of ultimate utilization. Construction of dangerous homemade electric gadgets must be discouraged; use of unauthorized appliances and devices must be discontinued. That these misapplications are often not apparent or remote from the ordinary paths of electrical engineers presents a challenge which must be accepted.

During the 13 years that the author has followed electric fencing but two human deaths involving commercial electric fence controllers have come to his attention. These occurred near Toppenish, Wash.[1] in 1937, and Pixley, Calif.[2] in 1944. Recently two independent searches by attorneys have located but two lawsuits involving electric fence accidents in which opinions have been filed in American state and federal appellate courts in the last ten years. One case concerned injury to a human being,[3] the other, the death of a mule.[4] Both litigations involved electric fences energized from homemade electric fence controllers.

Like all mechanical devices, the elec-

Paper 50-2, recommended by the AIEE Safety Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted April 4, 1949; made available for printing October 28, 1949.

CHARLES F. DALZIEL is Professor of Electrical Engineering, University of California, Berkeley, Calif.

The author wishes to acknowledge and thank O. H. Marchal, Directeur d'Administration, Ministere du Combustible et de l'energie, Bruxelles, Belgium, for his kindness in supplying much of the information regarding European practice. Acknowledgment also is given to various electric fence controller manufacturers for their co-operation in supplying information used in the preparation of this paper.

Table I. Electric Fence Industry

Taken from United States Census "Facts for Industry"

Year	Number Mfgrs. Reporting	Total Sales	
		Number Controllers	Value
1945	20	306,879	$2,834,349
1944	23	399,779	3,525,566
1943	23	440,102	3,267,416
1942		385,641	2,470,422

tric fence is not without its shortcomings. Stock must be trained to respect it. Small animals are difficult to fence electrically. Remote fences are hard to keep in operating condition. Brush and vegetation must be kept off the energized wires. Although a well-designed controller will handle 15 or more miles of fence, regardless of the length of the fence wire, unsatisfactory results may be experienced in places where the top soil is very dry, or during a heavy fog or light rain when the insulators are contaminated. The shock delivered by the fence should be more powerful and hence electric fencing should be more successful when used on irrigated lands, or in localities which receive summer rains in contrast to similar installations on the dry farms of the west or southwest.

Although not recommended for a property line fence or to restrain wild or ferocious animals, the electric fence is a valuable supplement to the conventional fence. It is cheaper and easier to erect. It provides a convenient movable barrier for controlling grazing. The ease with which the electric fence can be moved permits the subdivision of pasture land on which animals can graze progressively, thereby giving maximum efficiency in the use of the land for grazing. It has been found to be a valuable aid in the summer grazing of forest lands. When used in conjunction with the conventional fence it reduces maintenance by discouraging animals from riding down, pawing, gnawing, nuzzling, or uprooting permanent structures. The electric stock prod is a closely related application of the principles of the electric fence. Stock prods are valuable aids in the handling of animals in stock yards, slaughter houses, loading racks, and so forth.

The fundamental requirements of an electric fence are that it shall be effective and safe. The shock during poor grounding conditions, such as when an animal is standing on relatively dry ground, must be sufficiently powerful to repel him. On the other hand, the shock must be harmless to a child under all conditions. For example, an extreme case might be one in which the electrified wire was grasped with wet hands while the child was standing in a salt marsh. These two highly essential requirements of effectiveness and safety present difficult technical problems.

Because of the wide variation in the physical condition of individuals, it is impossible to design an electric fence which will be safe for all humans. The press contains frequent accounts of fatalities ascribed to heart failure caused by overexcitement, intense emotion, fear, or shock (that is, shock to the nervous system and not electric shock). For such susceptible persons, it is possible that contact with any electric circuit which permits currents only slightly in excess of the threshold of sensation might result in fatality. This possibility must be recognized, and in spite of what may be done to develop a safe electric fence, an occasional death is to be expected due to casual contact involving electric currents known to be safe for most normal individuals. Death in such cases should be considered due to shock and not to the primary effects of electric current.

All intermittent controllers impress a short shock which is followed by an off period during which time it is assumed that a human will release himself from the circuit. It must be recognized that failure to break contact with the fence wire may dangerously increase the hazard attending the use of these devices.

Many of the essential characteristics of electric fencing have not yet been determined. Neither the maximum shock safe for a small child nor the minimum shock required to control animals is known with certainty. The resistance between feet and ground and between the point of contact and the fence wire may vary from 1,000 to 2,000 ohms to values approaching infinity. Leakage resistance between the fence wire and ground due to wet dirty insulators is subject to wide variations, possibly from 10,000 to 20,000

ohms to infinity. However, in spite of this situation, electric fencing with approved controllers is giving satisfactory, economical, and safe service.

Patents covering electric fences date back to 1863, and several were issued between 1863 and 1934, the date generally regarded as the beginning of the electric fence industry. The magnitude of the electric fence industry at the present time in this country is evident from Table I, in which the number of manufacturers, number of units sold, and the dollar value, are given for the years 1942–1945. These data were taken from the United States Census "Facts for Industry." The year 1945 is the last for which figures are available. Manufacturers and distributors of electric fence controllers approved by the Industrial Commission of Wisconsin, dated April 28, 1948, are given in Table II, and a similar list approved by the Underwriters' Laboratories as of May 1948, are given in Table III.

It is interesting to note that most of the electric fence manufacturers are specialty houses or manufacturers of agricultural equipment; the large electrical manufacturers not having entered this field. The ready acceptance of electric fencing, following its commercial appearance in this country in 1934, resulted in some 200 manufacturers in 1938. Although many have not survived, only a fraction of the firms now engaged in the manufacture of controllers produce approved devices. Many concerns, especially the smaller ones, continue to manufacture controllers without formal compliance with any recognized safety code. In this regard it is indeed fortunate that the mortality rate is as low as it appears to be.

Types of Electric Fence Controllers

Types of electric fence controllers and required electrical characteristics are given in Table IV, wherein are summarized for comparative study, the essential output limitations of the three United States safety codes and similar regulations in effect in Finland, Denmark, Great Britain, France, and Sweden. Emphasis will be given to practices in this country, as only limited information is available regarding foreign developments. Although this procedure is necessitated by the lack of detailed information from foreign countries, it is believed that coverage of the subject should be satisfactory since electric fencing was in use here several years before it spread abroad. Foreign references state that the United States codes served as a basis for deliberation in all countries which have enacted legislation, and that all controllers fall into the four basic types covered by the National Electrical Safety Code.

Electric fence controllers may be classified in one of several ways, such as according to power supply, intended installation, and whether the output is continuous or intermittent. The power supply may be commercial alternating current or batteries (dry cells or storage battery). The controller may be designed for indoor or outside installation. The output may be noninterrupted, or it may consist of periodic impulses. Most commercial controllers are of the intermittent type.

Intermittent controllers may be provided with tapped transformer windings to permit adapting the output to various field conditions. A selector switch or several output terminals may be provided. Certain manufacturers claim that effectiveness is improved during conditions of high grounding resistance by operating at maximum voltage and reduced current,

Figure 1. Schematic diagram of an a-c intermittent electric fence controller

while during conditions of high leakage current, lower voltage and maximum current produce better results. Since the electric shock hazard depends solely upon the output current or quantity, and not voltage, the output limitations given in Table IV must not be exceeded under any conditions.

The chief electrical characteristics of the four types of controllers will be discussed in the paragraphs immediately following:

Intermittent A-C Output Type. The intermittent a-c controller consists of a high reactance transformer which is periodically energized from the 120-volt lighting circuit by an electrically-operated rotary or oscillating interrupter. Figure 1 gives a schematic diagram for such a controller. An oscillogram of the output from a commercial controller is shown in Figure 2.

A typical commercial intermittent a-c electric fence controller is shown in Figure 3. Depending upon the manufacturer, the output consists of 2 to 12 cycles of sine wave applied frequency, the first cycle or two of which may be asymmetrical. The open circuit voltage rarely exceeds 2,500 rms volts. The input circuit must be protected with a thermal cut-out arranged to disconnect the unit from the source should the interrupted contacts stop in a closed position or should a jumper be placed across the interrupted contacts (to protect against tampering). To protect the fence against transformer insulation failure it is required that the primary and secondary windings be placed on separate core legs so arranged that insulation failure will be to a grounded metallic barrier. One side of the output circuit, transformer core, and housing are connected to a common terminal and connected to an effective ground.

Figure 2. Oscillogram from an a-c intermittent electric fence controller

500-ohm noninductive resistor load

Inductive-Discharge Type. The inductive impulse controller is essentially an induction coil which is periodically energized from a low voltage d-c source by an electrically-operated rotating or oscillating interrupter. The output is similar to that produced by a jump spark ignition coil. The open-circuit voltage may exceed 10,000 crest volts. The d-c source may be rectified alternating current or supplied from batteries. Battery controllers are usually designed to operate three to five months between changes of dry cells or recharge of the storage battery. Some of these units are provided with a switch to permit operation on either batteries or 120 volts of alternating current which is transformed and rectified to battery voltage. A schematic diagram of a combination inductive impulse controller which may be energized from either 120 volts of alternating current or batteries is given in Figure 4. Figure 5 is an oscillogram showing the characteristic output wave form, and Figure 6 is a commercial unit.

A-c operated inductive impulse controllers must be protected with a thermal cutout, or equivalent device, and the steady current limited to 25 milliamperes, unless the construction inherently limits the maximum steady current under any condition, such as that caused by failure of the transformer or current interrupter, to 3 to 5 milliamperes. The 60-cycle trap in the output circuit of Figure 4 illustrates one method of complying with this requirement.

A battery compartment is usually provided in the controller housing for dry cell operated controllers, thereby making the unit entirely self-contained. Since the unit may be installed without regard to the availability of central station power, this type has been very popular and has enjoyed the greatest volume of sales.

Capacity-Discharge Type. The commercial capacity discharge controller is an intermittent device. The output of the capacity discharge controller is similar to the inductive-impulse type, except that transients caused by contact chatter are absent. The device consists of a moderate voltage rectifier which builds up a charge on a storage capacitor. When the voltage on the capacitor reaches a predetermined value, a trigger tube ionizes and suddenly discharges the capacitor through the primary of a pulsing transformer, the output of which is impressed between the fence wire and ground. This controller possesses the advantage of having no moving mechanical parts. However, it is costly, and at present it is of lesser importance in the highly competitive market.

A typical circuit diagram and an oscillogram taken from a capacity discharge controller are given in Figures 7 and 8 respectively. The storage capacitor is denoted by $C1$; $C2$ is a small blocking condenser, and V_1 is the trigger tube. Since the trigger tube remains conducting only during the discharge of $C1$, sustained current in the output is negligible. The circuit is essentially that of a relaxation oscillator, the frequency being fixed by resistance R.

An earlier and much simpler type of capacity discharge controller operated on the principle of energizing the fence wire directly from the charge stored in a capacitor. The essential elements were a high-voltage rectifier and a resistance input filter. The initial current in the discharge was limited to a safe value by a resistor in the output circuit; a second resistor in the rectifier circuit limited the

Figure 3. Typical commercial a-c intermittent electric fence controller

Figure 4. Schematic diagram of a combination inductive impulse electric fence controller

Figure 5. Oscillogram from a combination inductive impulse electric fence controller operated on 120 volts alternating current

Timing wave 100 cycles per second, 500-ohm noninductive resistor load

sustained output current. Although this type gave satisfactory results when the fence insulation resistance was high, it was found that the fence insulator leakage currents during ordinary conditions lowered the potential on the capacitor and seriously reduced the effectiveness of the electric fence. This type of controller has practically disappeared because of the serious reduction in effectiveness during slightly adverse operating conditions.

Continuous Type. The continuous electric fence controller is the simplest type, and consists of a high reactance transformer. Since no off period is provided, it is mandatory that the output current be sufficiently curtailed to permit a person to release accidental grasp of the fence wire by using muscles directly affected by the current. The maximum authorized current for the continuous electric fence is 8 milliamperes rms.

The continuous electric fence was popular in the early years of electric fencing. The electric shock hazard from such a device was pointed out by the author in his publications on let-go currents[44] in which it was shown that continuous 60-cycle alternating current of 8 rms milliamperes, although probably safe for normal men, would be dangerous to women and children. Since it is highly doubtful that lower currents would be effective in controlling animals, several concerns manufacturing continuous a-c electric fence controllers stopped production shortly after publication of these findings. To the best of the author's knowledge, the continuous type is no longer being marketed in this country.

Legislation Concerning Electric Fence Controllers

The number of fatalities due to contact with electric fences involving both humans and animals in the late 1930's reached such proportions as to constitute a problem of public safety. As a result, committees composed of representatives from agriculture, the electrical profession, and local, state, and federal agencies were organized to evaluate technical requirements and formulate safety regulations. The results of this effort produced three safety codes. These are General Orders on Electric Fences, Industrial Commission of Wisconsin, 1938; Standard for Electric Fence Controllers, Underwriters' Laboratories, 1939; and Safety Rules for Electric Fences, Part 6, Fifth Edition, National Electrical Safety Code, 1940.

Agricultural interests, much concerned with this problem, adopted in June, 1941, the following:

"WHEREAS loss of life has resulted from improper designs and installations of electric fencing equipment, and

"WHEREAS the National Bureau of Standards, the Underwriters' Laboratories, and several states have codes or standards for electric fence equipment which, so far as known, are safe, and

"WHEREAS a number of farmers, unmindful of the danger, are using various types of unapproved systems, which are believed to hazard human life, therefore be it

"RESOLVED that the American Society of Agricultural Engineers urge that greater efforts be made by the various interested agencies to further warn the public of the dangers involved in the use of such unapproved electric fence devices and installations, and that the Secretary of the Society be instructed to send copies of this resolution to the proper agencies of public regulation in each state."

Application and enforcement of these standards varies greatly in the several states. The Wisconsin statute provides that "every day during which any person, persons, corporation, or any official, agent, or employee thereof, shall fail to observe and comply with any order of the Commission. . . shall constitute a separate and distinct violation of such order, or of such sections, as the case may be." The Bureau of Labor, State of Oregon, requires compliance with the Underwriters' Standard. The Public Utilities Commission, State of Idaho, adopted Safety Rules for Electric Fences on August 15, 1940.

Although no specific legislation covering electric fences has been enacted by the State of California, such matters fall within the jurisdiction of the Department of Industrial Relations, Division of Industrial Safety. It is required that all appliances shall be of approved type. The Division will usually accept equipment and devices which have been approved by the Underwriters' Laboratories, United States Bureau of Standards, United States Bureau of Mines, and other institutions of recognized standing. The Division has jurisdiction only when employed labor is involved, with the exception of domestic servants, on federal reservations, and where the law delegates

Figure 6. Typical combination inductive impulse electric fence controller 120 volts alternating current or 6 volts direct current

other agencies. To date the Division has issued no list of approved controllers, yet electric fence controllers are available in stores throughout the state, and tens of thousands of electric fences are in daily use.

In the past there has been much heated discussion regarding the differences in the three codes. This controversy in technical circles has been unfortunate in that undoubtedly it has deterred adoption of any code in many states, and has created difficult problems for those individuals charged with enforcement in those states where regulations were in effect. As a result the average farmer, residing in a state not having specific legislation on electric fences and desiring to install an electric fence, has been left largely to his own resources. It is probable that he has been guided more by advertising than by the fact that a particular device carried or did not carry a certificate of approval. That construction of homemade controllers is still being considered by farmers is evident from the fact that during the period this paper was in preparation, the author received two requests for information regarding the construction of homemade controllers from persons on the eastern seaboard.

Just before the outbreak of World War II, the American Standards Association authorized the formation of a Sectional Committee on Electric Fences (*C-69*) to study the entire situation. Activity was suspended during the war, and the committee is still in the formative stages. However, it is anticipated that organization will be completed in 1950. In the interim, the National Bureau of Standards is setting up a committee on Test Methods and Apparatus in an endeavor to standardize methods of test and the instruments used to make them. It is anticipated that the Sectional Committee will review the accomplishments of this committee and deliberate on possible revisions of the various safety codes in the effort to arrive at more uniform requirements. It is hoped that ultimately the American Standards Association will make recommendations which will provide the stimulus to initiate specific legislation covering electric fences in the various states. Certainly the interest of public safety demands that this potentially hazardous device be controlled by specific enforceable regulations in all states, and thus put an end to the present unsatisfactory conditions which prevail over much of the country.

The almost zero mortality record of the past ten years in this country with approved electric fence controllers suggests that present regulations might be relaxed somewhat with resulting increase in effectiveness. With the single exception of the continuous a-c fence, Safety Rules for Electric Fences, National Electrical Safety Code, Part 6, Fifth Edition, paragraph *640D*, a reasonable compromise for a uniform code might consider the most liberal provisions of the three codes with advantageous results and without materially increasing the electric shock hazard.

Electric Fencing in Foreign Countries

Only limited information is available regarding electric fencing in foreign countries; however, recent inquiry indicates substantial interest in the subject. Although incomplete, Table V presents a list of standards, issuing authorities, and addresses both in this country and abroad. As mentioned previously, Table IV contains a summary of comparative output limitations. With the exception of the Underwriters' Standard, the similarity of the various codes is somewhat unexpected as one would hardly expect such substantial agreement between peoples otherwise having so many divergent viewpoints. Since similar studies comparing test methods and construction specifications would be of only limited interest, these will not be included here.

Figure 8. Oscillogram from a capacity discharge electric fence controller

Timing wave 10,000 cycles per second, 500-ohm noninductive resistor load

New regulations now are being issued in Norway. Previously, the output limitations for battery-operated controllers corresponded to the Danish regulations and a-c controllers were prohibited. Danish engineers have expressed much concern over the possibility that the high-voltage output might cause insulation breakdown of the transformer and thus permit the fence to become energized directly from the power circuit. This is of increased importance in Europe, since 220-volt lighting circuits are in general use. In contrast to American and French requirements that one side of the output circuit, transformer core, and controller housing be connected to the ground terminal, the regulations in Norway, Sweden, and Denmark require that both output terminals be insulated from the housing. In this case the protective ground for the housing and unenergized components is provided by the supply conduit. This requirement is intended to reduce high-voltage stresses should the controller ground become defective. In addition, all a-c operated controllers are limited to 5,000 crest volts on open circuit.

The opinion is held by many that battery-operated electric fence controllers are inherently safer than controllers energized from commercial power sources. This opinion is undoubtedly based on the possibility that insulation failure might cause the fence wire to become electrified without proper restraint. The various safety codes require that the primary and secondary windings of all a-c controller power transformers be placed on separate core legs, or otherwise separated, so that in case of failure of insulation the break-

down will be to a grounded metallic barrier. In addition, high potential dielectric tests, and safety cutouts or fuses are specified. It is generally recognized that lightning is the chief cause of insulation failure in well constructed controllers. Although separate lightning arresters connected to separate grounds provide the best protection, protective gaps or equivalent devices are provided in some controllers. This practice is highly recommended as an additional precaution. The importance of obtaining an effective ground must be emphasized. A low resistance ground is essential for protection against lightning, as well as insulation failures in general. In addition a good ground permits delivery of the maximum output, and thus assures maximum effectiveness in controlling animals. Possibly the opinion that battery controllers are inherently safer than a-c operated devices is also based upon the idea that the energy available from any device designed to operate from batteries which last three to five months cannot be very hazardous. While the author appreciates the logic behind this reasoning, such argument obviously fails if a manufacturer, oblivious to safety requirements, produces a device based on effectiveness only. In this connection it is pertinent to mention that in 1944 a human fatality occurred in Canada due to contact with an electric fence energized from a homemade controller supplied from a 6-volt battery. It is the author's opinion that when safety code requirements are followed, and the device is properly installed, the a-c operated electric fence controller should present no more of a hazard than other electrically-operated farm devices or household appliances.

To date, the Canadian Standards Association has refrained from taking definite action on electric fence matters; however, the electrical inspection departments of some of the provinces have approved battery-operated units. Nor has the Standards Association of Australia issued regulations, but it is reported that battery-operated controllers are finding increased use. Presumably local specifications are based on the British Standard for battery-operated electric fences.

The most recent action concerning electric fencing was that proposed at Copenhagen, Denmark. On October 15, 1948, the International Commission for the Regulation and Control of Electrical Equipment (CEE) adopted tentative Specifications for Electric Fence Controllers. The regulations adopted by this body, which was formerly known as Installations Fragons-Kommission (IFK), constitute the European counterpart of the National Electrical Safety Code in this country. Its recommendations, although not binding on the constituent member bodies, are intended to be used by legislative authorities in the various countries when drawing up their own national rules and regulations. The International Commission for the Regulation and Control of Electrical Equipment is composed of bodies, which in each of the member countries, in the interests of the public, especially with regard to safety, issue rules and regulations for electrical equipment and check compliance therewith. The countries concerned are Belgium, Czechoslovakia, Denmark, Finland, France, Hungary, Netherlands, Norway, Poland, Sweden, Switzerland, and the United Kingdom.

This new European tentative standard places the most rigid output limitations so far adopted. The effect of reduced shock intensity, particularly with regard to reduction of the impulse crest is of concern, since it is highly probable that these reduced limits will be incorporated in future revisions of the standards in the various member countries. The proposed standards were not accompanied by any comments relating to the reason for the downward revision of allowable current and quantity outputs. Possibly climatic conditions are more favorable in Europe, as normally precipitation occurs somewhat more evenly distributed throughout the year than in many sections of this country. The resulting improved grounding conditions may permit effective control with lower shock intensity than that believed essential for satisfactory operation in this country.

Almost without exception, the most serious adverse criticism of California farmers regarding electric fencing concerns effectiveness. Farmers desire a more powerful shock so that effectiveness may be better maintained during adverse operating conditions. Should the lower limits as proposed by the International Commission for the Regulation and Control of Electrical Equipment be adopted in this country, the value of electric fencing to the American farmer might be seriously jeopardized.

Conclusions

1. The approved electric fence is a safe, effective, and economical aid to modern farming.

2. Homemade electric fence controllers are responsible for the continuing electrocution of both human beings and animals. The use of such controllers should be prohibited by law.

3. The interests of public safety demand that specific enforceable legislation covering electric fence controllers be enacted in each of the various states of this country.

4. Need exists for uniformity in the various electric fence safety codes. With the exception of the continuous type of electric fence, it is doubtful if the differences in the present codes can be justified on the basis of safety. Although compromise in output limitations is necessary, it is essential that the maximum allowable output not be reduced materially, as any substantial reduction in effectiveness might jeopardize the value of electric fencing.

Development and Testing of an Improved High-Voltage, High-Capacity Impulse Circuit Breaker

E. B. RIETZ
ASSOCIATE AIEE

Synopsis: In October 1947, F. A. Lane and B. W. Wyman[1] described before the Institute the switchgear equipment developed for the Tidd High-Voltage Test Line. This equipment included a low oil content impulse-type circuit breaker rated 10,000,000 kva at 360 kv. The unit described at that time was part of an over-all development program of higher capacity switchgear equipments which will be needed to control and protect properly the rapidly expanding power systems of this country. This paper describes the development of the high-capacity impulse-type circuit breaker to be used in these equipments, both at existing transmission voltages and at the higher transmission voltages projected for the future. In addition, it presents substantiating laboratory and field test data indicating the ample margin of safety possessed by this circuit breaker to meet any requirements the future might dictate.

THE unprecedented expansion in electric load growth during and since the war has made it necessary for most power systems to operate close to their ultimate installed capacity, and many systems have had to be operated closer to their transient stability limit than would formerly have been considered good practice. Moreover, there is every indication that this rate of growth will continue for some time in the future. The result has been a tremendous increase in installed and planned generating capacity, with proportionate increases in paralleling transmission lines and greater interconnections between systems. Larger blocks of power than ever before are being transmitted over longer distances than ever before at existing transmission voltages, and the transmission of still larger blocks at higher voltages is being considered for the future.

Such an expansion in the power systems of this country cannot occur without placing new requirements on the high-voltage circuit breakers and switchgear used to control and protect these systems against short circuits.

Some of the new circuit breaker requirements are

1. The development of much higher interrupting capacities at existing transmission voltages.

2. The development of higher voltage ratings for use on the higher voltage transmission systems now under consideration.

3. The development of higher continuous current ratings.

4. The development of shorter reclosing times to permit reclosure as soon as the flashover paths are deionized. Present evidence indicates these times may be appreciably shorter than the present standard reclosing times of 20 cycles.

5. The development of circuit breakers with consistently short arcing times over the entire interrupting current range. This is increasingly important with the higher interrupting capacity circuit breakers contemplated, as the majority of faults they will interrupt may be some distance out on a line, and therefore less than 25 per cent of the interrupting rating of the circuit breaker.

6. The development of circuit breakers which do not restrike when interrupting the capacitive charging current of long transmission lines to eliminate the possibility of generating overvoltage surges which may cause line flashovers.

7. As the circuit breaker design determines, in large part, the design of the total station, its development must be co-ordinated with the over-all station so that it provides the best protection and switching at both a minimum first cost, and a minimum operating cost.

Of all the known types of high-voltage circuit breakers which might be developed to meet these requirements, the impulse-type low oil content circuit breaker had the most impressive test and operating

First break is most highly stressed with 25 per cent of total voltage

record. On the basis of this record, it was selected for development.

The impulse low oil content circuit breaker is not new. Fourteen years of outstanding operating experience have been obtained on the first impulse-type low oil content circuit breakers since they were placed in service on the 287-kv transmission line between Hoover Dam and Los Angeles. These circuit breakers were described before the Institute in June 1935.[2] As they were developed primarily to obtain high-speed fault isolation to increase the transient stability limit of that line, they had an interrupting time of 3 cycles. This was considered extremely high speed interruption at that time when most standard tank-type high-voltage circuit breakers had interrupting times of 8 cycles or longer. Besides increasing the system stability limit, the high speed fault interruption obtained with this type of circuit breaker resulted in reduced conductor damage at the point of fault, negligible voltage dips on the system, and negligible contact maintenance on the circuit breaker itself.

The design of these circuit breakers was a radical departure from standard tank-type high-voltage circuit breakers. The interrupters, instead of being submerged in large tanks of oil, were enclosed in small horizontal porcelain insulators. This construction eliminated over 90 per cent of the 15,000 gallons of oil required in tank-type circuit breakers and reduced the weight of the circuit breaker by more than one-half. Figure 1 shows one of these circuit breakers installed on the 287-kv Hoover Dam transmission line. Major savings were made possible with this circuit breaker in the cost of oil, and in the elimination of extensive oil-handling, filtering, and storage equipment.

Extremely high-speed arc interruption was obtained in these circuit breakers by using eight sets of cross-blast contacts located in the horizontal porcelain insulators. These contacts were divided into two groups of four, and separated in the center by two impulse pistons, one supplying a cross-blast of oil to each group.

Unlike tank-type circuit breakers, whose blast pressure is generated by the arc itself, and therefore varies with the current in the arc, these impulse circuit

Figure 6. Per cent distribution of total voltage between six breaks nonuniformly spaced to provide optimum distribution. First three breaks stressed almost uniformly

Figure 3. 230-kv low oil content impulse-type circuit breaker in service at J. D. Ross Substation of Bonneville Power System

Five sets of cross-blast contacts are located in horizontal interrupting unit with impulse oil blast piston located at upper right end. Eye-bolt current transformers replace cascade types of original designs

Figure 7. Horizontal interrupting unit of newly developed 360-kv low oil content circuit breaker

Six sets of series cross-blast contacts are enclosed in inner thick wall herkolite tube which carries entire weight of unit. Porcelain insulating shells are spaced concentrically around outside of herkolite tube as weather shields and are connected together by flexible metallic sylphons which prevent any load being transmitted to porcelains. Impulse oil blast piston which supplies oil blast to contacts is located in housing at ends. Large shielding rings at either end of interrupter improve distribution of voltage between various breaks

Figure 9. Complete 6-break contact assembly removed from interrupter for inspection on factory floor

Figure 10. Comparison of mechanism frame sizes between older type 230-kv spring-operated mechanism and new smaller 360-kv compressed-air operated mechanisms

breakers generated their blast pressure by the central piston, whose action was independent of the current being interrupted. Consistently short arcing times therefore were obtained whether interrupting either light load current or heavy short circuit currents. Special tests showed these circuit breakers to have extremely wide margins of safety above their rated interrupting capacity, both as regards voltage-interrupting ability and current-interrupting ability. Low oil content impulse circuit breakers of similar designs also were developed for other voltages soon afterwards. Figure 2 shows a 138-kv circuit breaker which is essentially one-half of the 287-kv circuit breaker with the operating rod in one of the vertical porcelain columns along with the cascade current transformer. The interrupting unit of this circuit breaker had four breaks, and its impulse piston was located at one end. With this arrangement, more uniform voltage distribution between the various breaks was obtained even with voltage shields omitted than was possible on the 287-kv circuit breaker, as a result of the elimination of the large piston housing in the center of the interrupter. The improved voltage distribution obtained with the impulse piston located at the end of the interrupter instead of the middle resulted in a 230-kv design with only five breaks, with the most highly stressed break having less voltage across it than the 8-break design at 287 kv. Figure 3 shows a 230-kv circuit breaker in service at the J. D. Ross Substation of the Bonneville Power System, in which external-type current transformers were used to replace the internal cascade transformers of earlier designs.

Although lower cost tank-type circuit breakers were used for the larger percentage of high-voltage switching applications between 1934 and the present time, large numbers of impulse-type circuit breakers have been installed in loca-

Figure 8. Cross section of complete single-pole of 360-kv impulse-type circuit breaker rated 10,000,000 kva showing six sets of cross-blast contacts in horizontal interrupting unit at top whose cross oil blast action is supplied by impulse piston in housing at left end

Both contacts and piston are driven through vertical operating rod directly connected to high-speed closing piston at bottom

Figure 11. Typical contact closing and contact opening curve showing the smooth high-speed closing action obtained with the air-operated mechanism

tions which demanded the utmost in interrupting performance over the entire range of interrupting currents, or where restriking during the interruption of capacitance charging currents of long transmission lines had to be eliminated, or where the reduction in maintenance oil-handling equipment, or fire hazard justified the higher cost of this type of circuit breaker.

Selection for Future Development

When it became evident some time ago, that circuit breakers for much higher interrupting capacities and higher voltage would be required in the near future, all the various established types of circuit breakers were reviewed to determine which type should be developed. By checking the impulse-type circuit breaker with other types against the list of requirements set forth earlier in this paper, it can be seen that the impulse circuit breaker best fulfills these requirements:

1. From the standpoint of interrupting ability, experience to date has shown no upper limit to the capacity for which impulse circuit breakers can be designed. Laboratory tests early showed that the 2,500,000-kva and 3,500,000-kva ratings which were assigned to previous designs did not represent anything near their actual interrupting capacity. This was born out by field tests at Grand Coulee Dam in 1947, when a 230-kv impulse circuit breaker installed in 1945 interrupted short circuits up to 6,700,000 kva without signs of distress, and gave every indication that it could have interrupted appreciably more, had more been available at that time.[4,5] Neither on line-charging currents nor on short-circuit currents did the circuit breaker exceed its rated 3.0-cycle interrupting time.

At the higher interrupting capacities under consideration, the extremely short arcing time of the impulse circuit breaker not only keeps the line damage at the point of fault to a minimum, but also reduces oil carbonization within the circuit breaker to a very low value. Moreover, as the range of currents to be interrupted from minimum to maximum becomes ever greater, the fundamental advantage of the constant blast pressure in the impulse circuit breaker assumes ever increasing importance. Although tank-type interrupters which generate their own blast pressure by the current in the arc can be developed to interrupt high currents without generating excessive pressures, they usually keep these pressures low by increasing the gas venting in the interrupter. This increased venting tends to compromise the performance when interrupting low currents as it reduces still further the low pressure generated at these currents.

Both impulse circuit breakers and the air-blast circuit breakers possess the desirable characteristics of constant blast pressure, but despite the large amount of development which has taken place, both here and abroad in high-voltage air blast circuit breakers, they cannot yet be considered for widespread application for the extremely high capacities, or high voltages required in the immediate future, whereas years of outstanding performance stand behind the impulse-type circuit breaker for voltages from 138 to 287 kv.

2. For higher voltages, one of the primary advantages of the impulse-type circuit breaker over the tank-type circuit breaker is its tremendous reduction in the quantity of oil required. As the diameter of the tank in tank-type circuit breakers must increase with voltage to maintain adequate clearance between the interrupters and the side wall of the tank, the difference in the quantity of oil required becomes tremendous at the higher voltages. Also, the usual loop arrangement of the interrupter, and the grounded steel tank surrounding them in the tank-type circuit breaker make good voltage distribution between the various breaks very difficult.

3. As higher continuous current ratings are required at the higher voltages under consideration for the future, the impulse-type circuit breaker has two distinct advantages over other types of circuit breakers. First, its contact stroke from the fully closed to the fully open position is only 25 to 35 per cent that of the tank-type circuit breakers; second, it has no heavy current-carrying crosshead. Both of these features reduce the energy required to produce the high-speed operation required. The reduction in contact stroke in the impulse circuit breaker is made possible by the improved voltage distribution between the series breaks by their straight line arrangement and by the elimination of the grounded steel tank.

4. As the original impulse circuit breakers antedated the advent of high-speed reclosing, they were operated by a mechanism which required several seconds to recharge before reclosing could take place. A complete new mechanism was therefore necessary to meet the requirement of high-speed reclosing. With this new mechanism provided, however, much faster reclosing times are possible with impulse circuit breakers than with tank-type circuit breakers for the expenditure of the same amount of energy, because of the reduced weight of contacts, the reduction in operating linkage, and the shorter stroke through which contacts and linkage must travel.

Figure 12. Simplicity of the new direct-connected piston-type air mechanism used for high-speed operation of 360-kv impulse-type circuit breaker

5. Minimum arcing times at all values of current are insured in impulse-type circuit breakers by the positive blast action of the impulse piston which starts simultaneously with the contacts. A substantial blast of oil pressure is therefore available before the instant of contact parting. As interruption then can occur as soon as current zero arrives, extremely short arc lengths result.

6. The elimination of restriking when interrupting line-charging current to prevent the possibility of generating overvoltage surges assumes increased importance with the present trend of building minimum cost transmission lines with reduced insulation levels. This is particularly true at 230 kv and above. The positive blast action of the impulse-type circuit breaker forces fresh oil between the contacts at the same rate whether the circuit breaker is interrupting line charging currents, or interrupting heavy short circuit currents. Therefore, no restriking can occur.

7. The impulse-type circuit breaker simplifies over-all station design by eliminating extensive oil handling, filtering, and storage equipment. Its reduced weight simplifies foundations, particularly when the station is located on marshy or filled ground, or close to river beds. The framework of the circuit breaker also may be used to support the overhead structure for mounting disconnecting switches, current transformers, or lightning arresters to simplify arrangement layouts.

Development of Improved Impulse Circuit Breaker

The first step in the development of higher-capacity higher-voltage impulse circuit breakers was the building of an experimental circuit breaker of the highest voltage and highest interrupting capacity then considered likely to be required in the next 5-to-10 year period. The interrupting and reclosing time were to be the shortest which would be required at any location. The maximum operating voltage likely to be used in the near future was selected as 360 kv, and 10,000,000 kva was selected originally as the maximum kilovolt-ampere interrupting capacity likely to be required, though it now appears that this will be substantially exceeded. After testing it to the limit of the laboratory, field tests were to be made, if possible, at higher values, as no laboratory facilities exist which permit testing to the full ratings assigned to this circuit breaker.

Through the courtesy and co-operation of the American Gas and Electric Service Corporation, arrangements were made to connect one pole of this circuit breaker with its complete switching unit to the Tidd High Voltage Test Line, which has the highest operating voltage in the country. This will provide voltage be-

havior data under actual field conditions.

Through the courtesy and co-operation of the United States Bureau of Reclamation, a second pole of this circuit breaker was given short-circuit interrupting tests at Grand Coulee Dam, which has the largest concentration of short circuit capacity of any location in the country.

The development of a higher-voltage higher-capacity impulse circuit breaker divided itself into two main categories.

1. The development of a higher voltage interrupter which also would be capable of interrupting the maximum current required of the new circuit breaker.

2. The development of a new high speed mechanism capable of reclosing in 10 cycles or less.

Higher Voltage Impulse-Type Interrupter

The fundamental oil blast equation stating the maximum rate of rise of recovery voltage a circuit breaker can interrupt equals the oil velocity multiplied by oil dielectric strength is simpler to calculate for the impulse-type interrupter than for any other known type, because the velocity of the oil from the impulse piston does not vary with the current in the arc. The number of breaks required for any given voltage is determined by the uniformity of the voltage distribution between breaks. In the original 287 kv impulse circuit breaker, with its large piston housing in the middle, the distribution of voltage between the eight breaks with one end grounded is shown in Figure 4. It will be noted that 25 per cent of the total voltage appears across the first break. The later 138- and 230-kv circuit breakers, however, with their piston housings located at the end of the interrupter showed considerably better voltage distribution, so that the latter arrangement was selected for higher voltage development. As the distribution of voltage between breaks is extremely difficult to calculate, a scale model interrupter was made up in which the number and spacing of the breaks could be varied as well as the size and shape of the shielding rings at the ends. This model showed that with six breaks uniformly spaced, and with enlarged shielding rings at the ends, the voltage distribution curve shown in Figure 5 could be obtained. Here, with only six breaks the voltage across the most highly stressed breaks is also 25 per cent, or the same as with the eight breaks in the 287-kv arrangement. The spacing of the six breaks was then varied nonuniformly by increasing the spacing between the center breaks giving

Figure 13. Single pole of 360-kv low oil content impulse circuit breaker set up for test in high power short circuit testing laboratory

a greatly improved voltage distribution which is shown in Figure 6. With this arrangement of breaks, it will be noted that the six breaks could be operated at 360 kv with the same voltage stress appearing across the worst break as in the original 8-break design, as can be seen from the following:

$$25 \text{ per cent of } \frac{287}{\sqrt{3}} = 41.6 \text{ kv}$$

$$20 \text{ per cent of } \frac{360}{\sqrt{3}} = 41.7 \text{ kv}$$

Although single break tests had shown this voltage to be extremely conservative for one break, it was decided on the basis of the large amount of excellent operating data obtained on previous designs, that this voltage should be retained for 360 kv. At 230 kv, considerably smaller shielding rings are used to reduce phase spacing. With these smaller shielding rings and somewhat poorer voltage distribution, five interrupting breaks are used.

Due to the increased length of the horizontal interrupting units which would increase the bending moment on the horizontal porcelains if they were rigidly mounted, the design of the horizontal unit was modified so that the porcelain insulators act merely as a rain shield. The entire weight of the interrupting unit and porcelains is carried on a thick-walled internal herkolite liner tube which forms the interrupting chamber. This herkolite tube has annular spacing rings around it to support the porcelain shells. Short oil-tight sylphons are then used to obtain an oil-tight joint between the porcelains, as shown in Figure 7. Figure 8, which is a cross-sectional view of the entire circuit breaker unit, shows the details of the contacts and impulse piston, with arrows indicating the flow of the oil blast out in the lower half of the herkolite tube and up between each set of contacts which part directly beneath ports in a horizontal dividing baffle. As each set of contacts and port forms a jet for the release of the oil pressure beneath the baffle, extremely high oil velocities are obtained between the contacts.

For contact inspection purposes, only the small volume of oil in the central herkolite tube, 90 gallons, in the 360-kv interrupter and 70 gallons in the 230-kv interrupter, need be drained before sliding the entire contact assembly out for inspection. The oil used for insulation between the outside of the herkolite tube and porcelain shell is isolated. Therefore, it need not be drained as it is not subject to arcing. Figure 9 shows a 360-kv contact assembly removed for inspection on the factory floor.

The contacts and blast piston are operated by a heavy insulation rod traveling up through the vertical operating column. The operating rod is carried through a mercury seal at the bottom of the vertical column which prevents leakage of oil. As in the horizontal unit, the vertical porcelain shells take none of the circuit breaker load, but merely act as rain shields with the inner thick-walled herkolite tube supporting the entire circuit breaker. As neither the vertical nor horizontal shells carry load, they are not subject to strain or vibration. Should they be broken accidentally, however, the oil inside the herkolite tubes would not be lost, and the circuit breaker could still be operated under emergency conditions until repairs could be made.

New High-Speed Reclosing Mechanism

The spring-type mechanism used on earlier impulse circuit breakers was not designed for high-speed reclosing. It was replaced, therefore, on the new circuit breaker by an air mechanism to obtain the highest possible reclosing speed. By locating this mechanism directly below the vertical operating rod, no linkage, cams, rollers, cranks, or gears were required. The piston used to close the circuit breaker was directly connected to the bottom of the vertical operating rod, as shown in Figure 8. The opening springs used to open the circuit breaker then were located at the far end of the horizontal interrupter at the other end of the contacts. A high-speed valve admits air to the top of the piston to close the circuit breaker. As it travels downward and

Figure 14. Complete single-phase switching unit shortly after assembly at Brilliant, Ohio for connection to Tidd High Voltage Test Line sponsored by the American Gas and Electric Company, showing construction of overhead structure for supporting disconnecting switches, through-type sealed bushings with current transformers and Thyrite lightning arresters

Figure 14(A). Artist's conception of complete triple-pole 360-kv switching unit including impulse circuit breaker motor-operated isolating switches with through-type sealed bushings and Thyrite-type lightning arresters

closes the contacts, it compresses the opening springs at the far end of the interrupter. When the circuit breaker is completely closed, a high-speed latch drops into position on top of the piston. When tripped, the springs at the far end of the interrupter open the circuit breaker. This arrangement has the important operating advantage of keeping all rods and links in the circuit breaker continually in tension, both during the closing and opening operations of the circuit breaker. Appreciably faster trip-free operation is obtained when closing on a fault than is possible with most circuit breakers whose operating rods are in compression in one direction and therefore cannot reverse their contacts until all lost motion, pin play, and deflections first are reversed. Immediate reversal, however, is possible with this mechanism. The reduction in mechanism size obtained by substituting the air mechanism for the old type spring mechanisms can be seen by referring to Figure 10, which shows the framework of one of the large spring mechanisms beside three frameworks of the small air mechanism. The low mass of the contact parts permits an easy control of the opening and closing speed. Figure 11 shows a typical closing and opening curve of the new circuit breaker.

The simplicity of the direct-connected assembled mechanism can be seen in Figure 12. Each pole is equipped with its own individual operator as it has been found that simultaneous operation of the three poles of high-voltage circuit breakers can be achieved reliably in this manner. Besides simplifying the circuit breaker construction and operation, individual pole mechanisms also make possible either single-pole or triple-pole reclosing without addition of extra mechanisms or linkages.

Laboratory Tests on 360-Kv Unit With Six Breaks

Figure 13 shows one pole of the 360-kv circuit breaker set up for test in the General Electric Company's high power, short circuit testing laboratory at Schenectady. The following data illustrate the results of the tests made on this unit.

1. Operating Times
   - Closing time = 8 cycles (250 pounds per square inch)
   - Contacts part = 1.5 cycles
   - Fully open = 5 cycles
   - Reclosing time = 8 cycles
2. Operating Speed
   - Closing = 9 feet per second at point of contact touching
   - Opening = 12 feet per second average for first 2 inches after contacts part
3. Life Tests
   - 1,000 reclosing operations
   - 1,000 trip-free operations
   - 1,000 close and open operations

   No faulty operations were observed during tests, and inspection after tests showed all circuits breaker and mechanism parts in excellent condition.
4. 60-Cycle High-Potential Tests—Rated 1-Minute Withstand = 590 kv
   620 kv (5 per cent over rating) withstood with circuit breaker open and closed.
5. $1^1/_2$ by 40 Microsecond Impulse Tests—Rated 1,300 kv
   - Maximum withstand test; Positive circuit breaker closed, 1,375 kv; circuit breaker open, 1,407 kv
   - Maximum withstand test; Negative circuit breaker closed, 1,650 kv; circuit breaker opened 1,550 kv
6. Interrupting Tests
   Table I lists a few representative interrupting tests made in the high power laboratory. The maximum voltage at which interrupting tests were made on the single-pole circuit breaker was 264 kv which is appreciably in excess of 210 kv which is phase voltage for 360 kv.

Connection to Tidd High-Voltage Test Line at Brilliant, Ohio

Following the laboratory tests, a single-pole unit was shipped to Brilliant, Ohio, and connected to the Tidd High Voltage

Test Line, sponsored by the American Gas and Electric Service Corporation. Figure 14 shows the assembly of the complete switching unit with its overhead structure supporting the disconnecting switches, through-type sealed bushings with current transformers and thyrite lightning arresters. The unit will be left on the line for extended periods through various types of weather before the test can be considered complete.

Tests at Grand Coulee Dam

A second pole unit of the circuit breaker was sent to Grand Coulee Dam for high-capacity short circuit tests on the 230-kv bus to which one, four, and eight 108,000-kw generators could be connected, plus three or six transmission lines. As two additional generators had been installed since the 1947 field tests on an earlier design impulse circuit breaker when 6,700,000 kva was obtained, it was expected that higher short-circuit currents would be obtained on these tests. The tests were scheduled during two weekends with the following objectives:

1. To determine the interrupting per-

formance of the complete 360-kv circuit breaker with six breaks.

2. To obtain sufficient interrupting data to determine the design of the 230-kv, 10,000,000-kva circuit breakers which are to be installed in the new switchyard on the other side of Grand Coulee Dam.

For this latter objective, provisions were made to short circuit first one break then two breaks in the 6-contact interrupter as a 230-kv circuit breaker would not require six breaks.

It was realized that the simple short circuiting of one and two breaks without changing the spacing of the other contacts or shielding rings would upset the ideal voltage distribution obtained with all six breaks. Tests made on this basis would be extremely conservative. Also, the port openings associated with shorted breaks were not plugged so that part of the blast pressure was lost through these ports; this also added to the conservativeness of the tests. Information also was desired on two weights of blast pistons, one a so-called light piston and the other a so-called heavy piston. Tests with two weights were desired to determine the effect, if any, which could be detected upon interruption by the slightly greater tendency of the light piston to slow down in the middle of a current loop, caused by the arc directly across the port entrances. The tests showed no noticeable difference in performance other than somewhat slower mechanical operation with the heavy piston.

The test set-up was similar to that used for the previous series, and is described in

detail in the paper, Field Tests for Development of 10,000,000-kva 230-kv Oil Circuit Breakers for Grand Coulee Dam Power Plant by C. L. Killgore and W. H. Clagett.[4] Figure 15 shows one pole of the 360-kv impulse-type low-oil content circuit breaker set up for test in Grand Coulee switchyard.

All faults were single-line-to-ground on *A* phase only, and were applied directly to the switchyard ground mat. Pretripping of the test circuit breaker was used to obtain maximum fault current in the arc by taking advantage of the rapid current decrement due to the effect of subtransient reactance during the first one or two cycles of fault current. Faults were applied for the opening tests by using as a closing circuit breaker the same impulse circuit breaker tested during the spring of 1947.

Test Results at Grand Coulee Dam

Five series of tests were made in two weekends. In the first series, Series *A*, Table II, five breaks were used with the heavy impulse piston. This series consisted of 23 tests interrupting the charging currents of from 100 to 328 miles of line. There were no restrikes on any test, and the maximum interrupting time was 2.2 cycles with an average of 1.93 cycles. Arcing times varied from 0.04 to 0.5 cycle.

In the first part of the next series of tests which were short-circuit interrupting tests, Series *B*, Table III, all six breaks were used. Thirteen tests, ranging from 500 to 7,280 megavolt amperes were obtained. One reclosing test set for 13-cycle reclosing time was obtained. Figures 16 and 17 show the contacts after the first part of this series. For the last part of the series, one outer end break was short circuited and 14 tests were made varying from 3,220 to 8,050 megavolt amperes. Ten of the tests were made at full capacity some of which were duty cycles. The last two tests were reclosing tests on arcing ground faults with the circuit breaker set for 13-cycle reclosing. In neither of these did the arcing ground reignite.

In the next series of tests, Series *C*, Table IV, the heavy piston was replaced by the light piston. A new contact unit was installed, and the two outer breaks were shorted out which gave very poor voltage distribution on the remaining four breaks. This series consisted of six line-charging and line-dropping tests on 100-mile and 200-mile line lengths. As restrikes occurred on two of the interruptions, indicating overstressing of one set of contacts, testing on this arrangement was discontinued.

In the next series of tests, Series *F*, Table V, the short circuit was removed from one of the sets of contacts, and 15 line-charging and dropping tests were made on line lengths from 100 to 382 miles with the light piston. Again there were no restrikes, and the maximum interrupting time was reduced to 1.7 cycles with arcing times varying from 0.05 to 0.5 cycle.

The next series, Series *D*, Table VI, was made on the same arrangement (five breaks and light piston), but were short-circuit interrupting tests. Eighteen tests were made from 500 to 8,680 megavolt amperes with interrupting times from 1.8 to 2.8 cycles. Ten of these were at full capacity including a standard close-open +15 second+close-open duty cycle, and three reclosing duty cycles with reclosing times down to 8.6 cycles. There was no disturbance evident, and the contacts were in good condition after tests. Figures 18 and 19 show the contacts. The last of this series was made with an additional break again short circuited leaving four breaks. Fourteen tests were made with duties varying from 3,400 to 7,460 megavolt amperes. The interrupting times varied from 1.8 to 2.9 cycles. Ten tests

Figure 22. Oscillogram of test number 8R1, series *D*, showing reclosing fault duty on low oil content impulse circuit breaker at Grand Coulee switchyard interrupting 8,700,000 kva on first operation with 2 cycles interrupting time and reclosing 8.6 cycles

Figure 23. Oscillogram of test number 17, series *D*, showing interruption of arcing ground fault followed by successful reclosing without re-establishment of arcing fault in 9.7 cycles with low oil content impulse circuit breaker. Interrupting duty on this test was approximately 6,800,000 kva with total de-energized time 7.7 cycles

were made at full capacity, including a standard close-open+15 second+close-open duty cycle, and instantaneous reclosing duty cycles with the circuit breaker set for 8.5-cycle reclosing. The last two full capacity tests were made with arcing grounds, one with 8.6-cycle reclosing time, and in neither did reignition of the flashover occur. The de-energized time of the fault was 6.8 cycles. There was no disturbance during the tests, and after the test the contacts were in excellent condition.

Summary of Test Results

These tests indicated no difference in arc interrupting performance between light and heavy pistons. As faster opening, closing, and reclosing times are obtained with the light piston, it will be used in future designs. With the light piston, no interrupting times exceeded 2.9 cycles, either in factory tests or field tests.

Ultra-high speed reclosing tests up to 8,680,000 kva were obtained with 8.6 cycles reclosing which, so far as is known by the author, has not been duplicated on any other type of circuit breaker. Arcing ground tests showed no tendency for re-establishment of a high capacity flashover on an insulator string in the station after a dead time of only 6.8 cycles. It cannot be assumed from this test that the same successful reclosing time would have been obtained if capacitive coupling had been present. The field performance of the circuit breaker on single-phase line-to-ground tests up to an equivalent of 8,680,000 kva at 230 kv indicated it could have handled 10,000,000 kva with ease. As these tests duplicate high power laboratory tests at lower voltage almost exactly up to this value, it also may be assumed that tests up to 25,000 amperes also would duplicate laboratory tests at 25,000 amperes, which would result in an interrupting capacity in excess of 10,000,000 kva. An equivalent interrupting current at 360 kv on the 6-break design would result in an interrupting capacity of over 15,000,000 kva.

No restriking was obtained even when switching 382 miles of line with five breaks despite the poor voltage distribution obtained with one break in a 6-break unit short circuited. Restriking was en-

Figure 24. Artist's conception of one of the nine complete switching units being built for new switchyard at Grand Coulee Dam with supporting structure for disconnecting switches, through-type bushings, and current transformers mounted directly on circuit breaker framework

countered, however, with four breaks, though it probably would not have been if better voltage distribution between breaks could have been obtained on the sample unit which had some breaks short-circuited. To be conservative, however, five breaks were selected for the 10,000,000-kva circuit breakers being built for the new switchyard at Grand Coulee Dam.

Figure 24 shows an artist's view of one of the nine complete switching units being built for this application using impulse circuit breakers with the overhead disconnecting switches and current transformer structure carried directly on top of the circuit breaker frame.

Conclusions

For higher interrupting capacities at existing transmission voltages and for higher voltages, the impulse-type low-oil-content circuit breaker has a number of important advantages. Laboratory and field tests for 10,000,000-kva designs at 230 and 360 kv have been made, showing it capable of meeting without exception, all the requirements desirable in a circuit breaker for the protection of the higher capacity power systems of the future.

Discussion

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The low-oil-content impulse-type circuit breaker appeared 15 years ago as a challenge to the conventional dead-tank construction for the highest voltage circuit breaker ratings. The excellence of its original design is indicated by the relatively few modifications that have been made since, the principal improvement disclosed in this paper being the substitution of a modern pneumatic mechanism suitable for rapid reclosing in place of the earlier motor-wound spring-type operator.

In spite of its generally satisfactory performance record, the impulse circuit breaker has failed in all these years to supplant the reliable steel-tank circuit breaker. In fact, the manufacturers of the impulse circuit breaker, recognizing its limited field of application to special high-voltage and high-interrupting capacity installations, brought out recently a completely new and redesigned line of conventional dead-tank circuit breakers for voltages up to 230 kv. Furthermore, reports from England indicate that throughout Europe where the low-oil-content circuit breakers have found wide-spread usage, the trend now is definitely away from this construction in favor of air-blast circuit breakers for even the highest voltage ratings.

Over ten years ago, a 138-kv low-oil-content porcelain-clad circuit breaker was designed and built in this country.[1] An experimental unit was tested successfully to more than 2,000,000 kva on a large 230-kv power system, but limited applicability in competition with standard circuit breakers made it inadvisable to use this design commercially. To avoid an obviously undesirable situation in the industry of having three entirely different types of high-voltage circuit breaker construction for identical ratings, it is necessary now to consider carefully whether this reappearance of the low-oil-content circuit breaker actually represents a new lease on life to fill requirements impossible to meet with the other types, or whether it is only an interim design destined eventually to be superseded.

The disadvantages of inherently high cost and unsuitability for inclusion of current transformers and potential taps within the circuit breaker structure are pointed out in the paper. The mounting of separate through-type bushings in the overhead structure to provide for necessary current transformers involves additional steel work that may or may not fit into a particular station layout. Claims of improved interrupting performance in comparison with conventional dead-tank circuit breakers may apply in the case of certain older designs which require low-ohmic resistors to bolster up their erratic operation. However, the most modern multiflow interrupters equipped with auxiliary oil-flow pistons are restrike-free when opening line-charging current, and are capable of interrupting the highest interrupting capacities required by industry without particularly heavy mechanism loading.

While the inertia of the moving parts of the impulse circuit breaker may be less than the corresponding steel-tank design, it is evident that very powerful springs must be necessary to drive the impulse pistons against the back-pressure of the heaviest short-circuit currents since each pole of the circuit breaker is provided with a separate operating mechanism, any one of which is large enough to close all three poles of a conventional circuit breaker.

The statement has been made before and is repeated again in this paper that "the velocity of the oil does not vary with the current in the arc." No satisfactory data has been presented to substantiate such a statement, and in fact other discussion in the paper definitely indicates that the opposite is true. For instance, in explaining the reasons for testing with either a light or a heavy piston, it is admitted that there is a "slightly greater tendency of the light piston to slow down in the middle of a current loop, caused by the arc directly across the port entrances." The observation that there was no appreciable effect on the interrupting performance on a particular series of tests does not change the fact that a temporary slowing up of the oil velocity does take place during the arcing period. The possibility of the piston even backing up due to excessive arc pressure is recognized by the provision of a check valve in the flow channel between the piston and the contacts. It would be interesting to know whether any tendency to stall the piston would also result in slowing down the contact motion.

The use of horizontal insulating surfaces between live parts under oil generally has been considered undesirable because of the possibility of creepage breakdown due to the presence of carbon particles settling out of oil that has been subjected to arcing. I should like to ask the author whether impulse circuit breakers have ever been used in tie-line positions between two systems that have operated for a time out-of-synchronism subjecting the circuit breaker to a low-frequency potential difference of twice normal voltage.

It is gratifying to see such a large amount of test data from both laboratory and field tests included in the paper. Repeated testing is, of course, the best guarantee of reliable performance. However, it is unfortunate that in verifying a multibreak device in the laboratory, the old method of extrapolation to higher powers should still be used, that is, interrupting at rated voltage low currents amounting to only a fraction of the circuit breaker rating, and then interrupting rated short-circuit current at only a fraction of the rated voltage. For instance, the 25,000-ampere interruptions of Table I would be much more convincing if cleared by one break only. (From Figure 6, the most highly stressed break in a 360-kv circuit breaker will have to handle 20 per cent of the line-to-ground voltage, or 42 kv). Instead, all six breaks in series were used to open a 14.5-kv circuit which is less than 1/14 of rated voltage. The arcing times at this low voltage were only two-thirds of the times at 264 kv, indicating that the performance shown can hardly be considered representative of what the circuit breaker would do at full voltage and full power.

As an example of what would seem to be a more justifiable extrapolation, I should like to mention recent laboratory tests on a steel-tank high-voltage circuit breaker equipped with 360-kv multiflow grid interrupters. Short-circuit currents of 17,200 amperes at 88 kv, 12,100 amperes at 110 kv, and 11,000 amperes at 132 kv across one-half of the pole unit were interrupted successfully in less than 3 cycles, representing direct tests at the appropriate voltage and current equivalent to 3-phase faults of 8,000,000 to 9,000,000 kva at line voltages of 305, 380,

and 460 kv respectively. This would seem to indicate that the steel-tank circuit breaker is not yet an extinct species.

REFERENCE

1. THE VERTICAL FLOW INTERRUPTER AND ITS APPLICATION TO OIL-POOR CIRCUIT INTERRUPTERS, B. P. Baker, *AIEE Transactions*, volume 60, 1941, pages 440–45.

Otto Naef (American Gas and Electric Service Corporation, New York, N. Y.): In the description of the interrupter, it is stated that the velocity of the oil from the impulse piston does not vary with the current in the arc. This statement seems to me to require some clarification. The back pressure generated by the arc undoubtedly tends to retard the movement of the impulse piston, whereas, it may add to or subtract from the force which opens the contacts, depending on how the design is worked out. The velocity of the oil flow and the opening speed of the circuit breaker is a function of both influences, as well as of the kind of coupling, rigid or flexible, between impulse piston and contacts. Some more detailed information on this point will be appreciated, as it will help to estimate the performance of the circuit breaker under conditions of unusual severity in excess of the circuit breaker rating.

Figure 6 of the paper shows an improved voltage distribution between six breaks nonuniformly spaced. Provided the lengths of individual breaks vary, it would appear that this voltage distribution is only obtained in the fully open position of the contacts and not at the moment of arc extinction.

With other types of circuit breakers, trouble has been caused by the formation of leakage paths on horizontal insulating surfaces rendered semiconductive by deposits of carbon. It has therefore been considered sound practice to arrange insulating surfaces only vertically between parts which are continuously at different potentials. In the impulse circuit breaker, the insulating tube and the plate carrying the ports are in a horizontal position and under continuous voltage stress when the circuit breaker is open.

Although the production of carbon and sludge is undoubtedly much smaller than in older circuit breakers and the contacts are normally closed, which removes the stress, it will be interesting to learn whether tests have been made to determine the intervals in which these parts must be cleaned.

E. B. Rietz: I would remind Mr. Leeds that most of the questions raised in his discussion are familiar to us, and probably better realized because of the many years that we have been making impulse circuit breakers. When he speaks of the failure of this circuit breaker to supplant the tank-type circuit breaker, it is still possible that this can be due to the fact that the low-oil-content-type of circuit breaker is still ahead of its time and is not recognized in its rightful position. Certainly, there are economic limitations. We are striving to overcome them and feel that considerable progress has been made in the last few years.

There are still the three general types of circuit breaker for this field. The question of whether a low-oil-content circuit breaker or a compressed-air circuit breaker will be the circuit breaker of the future is still unknown. Both circuit breakers have similar structures and have somewhat the same limitations. However, the oil circuit breaker is self-contained in the sense that a reliable source of air is not required for interruption. Likewise, there is more experience with this type of circuit breaker. It also would seem that the known susceptibility of air-blast circuit breakers to high voltage recovery rates is not a serious problem with the oil circuit breaker.

I would question the limited applicability of a low-oil-content impulse circuit breaker because for many years these were used interchangeably with tank-type circuit breakers. When furnished without a complete switching unit, they are just as applicable as far as we can see. Indeed, they are just as applicable as any air-blast circuit breaker which Mr. Leeds seems to prefer.

The desirable operating characteristics of the impulse circuit breaker on line switching has not been equaled by any tank-type circuit breaker as far as the published literature shows. The impulse circuit breaker has no restrikes, while as far as we have been able to observe tank-type circuit breakers do have restrikes, but they can be controlled so as not to give rise to abnormal overvoltages.

The reference to oil velocity in the paper is intended to stress the fact that regardless of the current to be interrupted, there is always the same oil velocity previous to the drawing of the arc. Mr. Leeds is quite right that there may be a hesitation of the oil piston on high duties. The use of both light and heavy pistons on the field tests was to observe the effect. It was observed that the interrupting performance was equally satisfactory with the light piston on which there was some hesitation. The contact design is such that this is no effect on the opening speed of the contacts, therefore, it does not affect the interrupting performance.

Special precautions have been taken to obtain maximum creepage between the series contacts to provide adequate insulation across the horizontal interrupting unit. It should be remembered that the contact parts are located on the underside of the board and are actually spaced away from the board. Therefore, the creepage paths are much larger than I believe generally expected.

Some 16 years of experience with 60 to 70 circuit breakers would seem to indicate that this feature has been adequately covered in the design.

We do not question the fact that a tank-type circuit breaker is still in the picture for this class of service. We merely intend to point out that the low-oil-content impulse circuit breaker should be considered in future thinking as it appears to have advantages which will ultimately cause it to supplant tank-type circuit breakers.

Mr. Naef's discussion covers a number of the same points referred to above and I think requires no further comments.

The Direct Measurement of Bandwidth

CHARLES R. AMMERMAN
ASSOCIATE AIEE

EVER since the field of communications had its beginning, the width of the band of frequencies that could be passed by any piece of equipment has been important. Advances in the field have put more rigorous demands on the fidelity of response of some systems, consequently requiring greater pass-bands and at the same time progress has demanded that other systems become more and more selective with an appropriate limitation of pass-band. Notwithstanding, the specification of bandwidth is not standard, nor has its measurement been greatly simplified.

Traditional methods of bandwidth measurement are based on somewhat arbitrary specifications, for example, the frequency difference between the high and low frequencies at which the single-tone response provides half the power corresponding to the frequency of maximum response. Other definitions of bandwidth or cut-off frequency are used in special cases whenever they seem appropriate. The lack of standardization in this matter creates confusion which is only now being resolved by the concept of equivalent bandwidth. A review of this concept is given to facilitate discussion of the measuring instruments described.

The Concept of Bandwidth

In consideration of band-pass devices, it is often convenient to think of an ideal frequency response curve. The response would be uniform between the cut-off frequencies, and zero above and below the cut-off frequencies. Figure 1(A) represents such an ideal case. Here f_1 is the low-frequency cut-off, f_2 is the high-frequency cut-off, and A_0 is the amplification of the device in the pass band. (In this discussion amplification will be considered the magnitude of the ratio of the output voltage to the input voltage.) In the ideal case there can be no doubt about the meaning of the term bandwidth; it is simply f_2-f_1.

Figure 1(B) represents a generalized response curve of the type often found in actual practice. The amplification, instead of being either A_0 or zero, is some function of frequency, $A(f)$. There are no real cut-off frequencies, because the amplification approaches zero rather slowly at both extremes. The amplification A_0, also is somewhat indefinite. Often $A(f)$ has a broad maximum, which usually is designated the amplification. Even if the maximum is sharp, as in a tuned network, the amplification is taken as the maximum value of $A(f)$. If $A(f)$ is rather irregular, it may possibly be desirable to use a different definition of A_0, but for the purposes of this paper A_0 will be defined as the maximum value of $A(f)$.

The specification of bandwidth of this network is more difficult. Previous methods have followed the procedure of deciding how much variation of $A(f)$ is significant and placing the frequency limits at these points, for example f_a and f_b. (Half-power points are often used.) Since the determination of significant variation usually is subjective, this is not so satisfactory. Another important point in the specification of bandwidth arises in connection with the acceptance of noise by a receiver. The bandwidth of the receiver determines the noise power in the output, and consequently affects the signal-to-noise ratio. This fact makes it especially important to consider noise in defining bandwidth.

For all these reasons it is desirable to specify bandwidth in terms of the ideal response shape of Figure 1(A) which is equivalent to the practical response shape of Figure 1(B). This equivalence is based on the power output resulting from a random noise input.

Random Noise

Random noise, fluctuation noise, or "white" noise has a constant power density spectrum. That is, it is composed of equal components of voltage of all phases and frequencies. A random noise may be produced in several ways, all of them exploiting the randomness of certain electronic phenomena. Shot noise and thermal agitation noise are examples; other sources of noise will be discussed later, but the point is that a noise can be produced having a uniform spectrum at least over a range sufficiently wide for most measuring purposes.

Mathematically random noise can be written

$$\begin{aligned} e = {} & E \sin[\omega_0 t+\varphi_0] + E \sin[(\omega_0+\Delta\omega)t+\varphi_1] + \\ & E \sin[(\omega_0+2\Delta\omega)t+\varphi_2] + \\ & E \sin[(\omega_0+3\Delta\omega)t+\varphi_3] \ldots\ldots + \\ & E \sin[(\omega_0-\Delta\omega)t+\varphi_{-1}] + \\ & E \sin[(\omega_0-2\Delta\omega)t+\varphi_{-2}] + \\ & E \sin[(\omega_0-3\Delta\omega)t+\varphi_{-3}] \ldots\ldots \quad (1) \end{aligned}$$

where E is the magnitude of one of the harmonic components (all equal), $\Delta\omega$ is the radian frequency difference between components, and φ_n is a completely random phase angle.

A very thorough discussion of the statistical character of random noise has been written by S. O. Rice,[2] while E. B. Moullin[3] presents the physical side of many noise phenomena.

Equivalent Bandwidth

The equivalence of the practical and ideal networks regarding response to random noise or uniform power spectrum is developed by equating the noise power outputs. If a single tone of voltage E and frequency f be impressed on a practical net-

Paper 50-5, recommended by the AIEE Joint Subcommittee on Electronic Instruments and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 31, 1949; made available for printing November 21, 1949.

CHARLES R. AMMERMAN is with the Electrical Engineering Department, Pennsylvania State College, State College, Pa.

Appreciation is expressed to Dr. V. M. Albers and Dr. A. H. Waynick for their interest and aid in this problem.

Figure 1. (A) Frequency response of idealized band pass network. (B) Frequency response of practical network

work, the output power will be $E^2A_{(f)}^2/R_1$ where R_1 is the termination of the network. Also n single tones will produce a voltage of

$$\sum^{n} E_n^2 A_{(f)}^2/R_1$$

A noise spectrum will have an infinite number of equal components and the power output will be

$$P_0 = \int_0^{\infty} \frac{E^2 A_{(f)}^2}{R_1}\, df \qquad (2)$$

The ideal network will be similar except that the integral will be zero between 0 and f_1 and between f_2 and ∞, and between f_1 and f_2 the amplification is A_0. For this case

$$P_0 = \int_{f}^{f_2} \frac{E^2 A_0^2}{R_1}\, df \qquad (3)$$

R_{11} = 55,000 ohms	C_4 = 0.1 microfarad	L_2 = peaking coil
R_{12} = 6,900 ohms	C_5 = 0.1 microfarad	L_4 = 250 millihenrys

A_0 for the ideal network is equal to A_0, or the maximum value of $A_{(f)}$, for the practical network.

Equating the power outputs and eliminating E and R_1 which are not functions of frequency and are the same for both networks

$$\int_0^{\infty} A^2_{(f)} df = \int_{f_1}^{f_2} A_0^2 df = A_0^2(f_2 - f_1) \qquad (4)$$

Hence the two networks are equivalent if

$$(f_2 - f_1) = \int_0^{\infty} \frac{A_{(f)}^2\, df}{A_0^2} \qquad (5)$$

That is, $f_2 - f_1$ is the equivalent bandwidth of the practical network.

To determine equivalent bandwidth using this definition it is necessary to perform the integration of the squared frequency response curve. This can be accomplished in three general ways.

First, of course, the integration can be accomplished mathematically if the mathematical form of $A_{(f)}$ is known and if the integration can be carried out. One example of this is a pentode supplying a parallel resistance-capacitance circuit with essentially constant current. Mathematical evaluation of equation 5 gives bandwidth $= 1/(4RC)$. For more complicated cases the difficulty of this process becomes excessive.

A graphical-mechanical method can be used to perform the integration. A graph of $A_{(f)}^2$ is plotted, point by point, using data obtained with a continuous wave signal. The area then is found by counting squares or using a planimeter. The effective bandwidth is this area divided by the maximum value of $A_{(f)}^2$. This system is used widely but is tedious and time-consuming, and herein lies its disadvantage.

The third general method is to set up the unknown network and compare its noise power output to that of a standard network. By properly doing this, the bandwidth may be measured directly. The block diagram showing the needed apparatus is shown in Figure 2. The continuous wave variable frequency oscillator and the noise source are arranged so that the input to the two networks will be the same. The voltmeter reads the output voltage of either network using either source. The voltmeter must be suitable for the measurement of noise voltages; that is, its frequency range must be sufficient to encompass all components in the output of either network and its indication must be proportional to power or rms voltage.

If a certain noise voltage E_i is applied to standard network, the voltmeter reading will be

$$E_{os}^2 = E_i^2 A_{os}^2 BW_s \qquad (6)$$

E_i is the noise input voltage; A_{os} is the maximum amplification of the standard, and BW_s is the bandwidth of the stand-

ard. If the same noise voltage is applied to the network being tested, the voltmeter reading will be

$$E_{os}^2 = E_i^2 A_{os}^2 BW_x \tag{7}$$

Here A_{os} is the maximum amplification of the unknown and BW_x is the bandwidth of the unknown. The ratio of these is

$$\frac{E_{os}^2}{E_{ss}^2} = \frac{A_{os}^2 BW_s}{A_{ss}^2 BW_x} \tag{8}$$

Solving for the bandwidth of the unknown

$$BW_x = \frac{E_{os}^2}{E_{ss}^2} \frac{A_{ss}^2}{A_{os}^2} BW_s \tag{9}$$

The ratio A_{os}^2/A_{ss}^2 is the ratio of the voltmeter readings of the two networks using for each network the frequency of maximum amplification (input voltage constant). The ratio E_{os}^2/E_{ss}^2, as in equation 9, is the ratio of voltmeter readings with equal noise voltages. BW_s is calculated by the graphical-mechanical means outlined above.

General requirements for the measuring equipment having been set, consideration now will be given to the specific items of equipment. Each of the units shown in Figure 2 is discussed separately; connection and switching is accomplished by a coupler-comparator unit.

Noise Generator

There are many suitable sources of noise, each having its own peculiar advantages and disadvantages. The ultimate choice of the noise source will probably be a matter of convenience and availability, and in this case a noise generator from a modulator for a radar jamming set used by the armed forces proved to be the most convenient starting point. Certain modifications were made to make it more useful, and the complete circuit is shown in Figure 3.

The photoelectric cathode, secondary-emission multiplier tube is a source of fairly high-level noise. Noise in a photoelectric diode is similar to the shot noise in a temperature-limited diode. The rms noise current is[1]

$$I = \sqrt{2eI_{dc}\Delta f} \text{ amperes}/\sqrt{\text{cycle}} \tag{10}$$

where e is the charge on an electron, I_{dc} is the average current, and Δf is the bandwidth. This noise is amplified and slightly augmented in the multiplier sections.[5] Consider a type *931-A* tube with a current amplification of 10^6 and a maximum d-c anode current of 10^{-8} amperes at rated conditions. The photocathode current is therefore 10^{-9} amperes at rated conditions, and the noise component in the photocathode current is

$$I = 5.6 \times 10^{-18} \text{ amperes}/\sqrt{kc}$$

This is amplified by 10^6 and slightly increased, so that this may produce a noise current of 6×10^{-8} amperes/$\sqrt{kc}$ in the anode circuit. Suppose the anode load resistance is 3,000 ohms; this will produce a noise voltage of 18 millivolts per $\sqrt{kc}$. Very little amplification is necessary to make this useful for present purposes. The circuit in Figure 3 shows two stages of video amplification and a cathode follower output stage.

The frequency range of this generator is important. The high-frequency response of the video amplifiers is good to nearly 4 megacycles. The low frequency response is poor, particularly because of the coupling circuit between the *931-A* and the *6AC7*, for which the 3-decibel point is approximately 42 kc. This did not constitute a serious objection in the work done in this case; however, it is felt that a noise generator with uniform

Figure 6 (right). Frequency response of voltmeter

Figure 5. Calibration curves of voltmeter with sinusoidal input voltage

output down to 1 kc would be desirable should another noise source ever be built.

The output in a generator of this type can be controlled by varying three quantities: the current through the exciter lamp; the voltage on the secondary-emission multiplier; or the gain of the amplifier. Both of the first two methods were used in this work.

One distinct disadvantage of the secondary emission multiplier is the change in amplification with the change in multiplier voltage. Examination of the published curves for the *931-A* reveals that a reduction of 5 per cent from rated voltage results in a reduction of 30 per cent from rated amplification. Close control of anode voltage during a test is therefore necessary.

Continuous Wave Generator

Any signal generator with frequency range including the frequencies of maximum response of standard and unknown networks, and having sufficient output voltage, may be used here.

Voltmeter

A voltmeter of wide frequency range, reading rms values (or proportional to the average power) must be used in this setup. In the voltmeter constructed, use is made of the nonlinear region of the grid voltage-plate current characteristics. By proper selection of the operating range, a characteristic is obtained such that the meter deflection is proportional to the square of the input voltage.

The instrument is based on a square-law voltmeter described by J. R. Ragazzini and B. R. Boymel.[4] A few minor changes were incorporated, and the circuit is shown in Figure 4.

Figure 8. Squared amplification versus frequency for standard network

The criterion for square-law operation is that the grid voltage-plate current curve shall be expressible by the equation

$$I_p = I_o + aE_g + bE_g^2 \tag{11}$$

The simplest way to locate this region is to make use of a mutual conductance bridge.

$$g_m = \frac{\partial I_p}{\partial E_g} = a + bE_g \tag{12}$$

If g_m is plotted against E_g, the region where the graph is a straight line will be the region where equation 11 is satisfied. Since it is reasonable to expect negative variations as great as positive variations, the grid bias is set in the middle of this region. For the tube used, a bias of -1.7 volts is necessary.

The range of the voltmeter is shown in Figure 5. Here the deflection is plotted against the square of the rms value of a sinusoidal input voltage. It is seen that

Figure 9. Squared amplification versus frequency for one intermediate-frequency transformer tested

deviation from square law increases slowly. It was felt that a 10 per cent deviation at the peaks would not be detrimental; in that case the range of the instrument is approximately 1.0 volt rms sine wave or 1.4 volts peak. If the voltmeter is operated at maximum sensitivity and approximately midscale the rms voltage is approximately 0.44 volt compared to 1.4 volts peak allowable.

The probability of the absolute value of instantaneous noise voltage exceeding a value r times the rms value is given by[5]

$$p = 1 - erf\left(\frac{r}{\sqrt{2}}\right) \tag{13}$$

where *erf* is the error function. If $r = 1.4/0.44$; $p = 0.00146$.

That is, the noise voltage will exceed the voltmeter range only approximately 1/700 of the time. It is felt that serious error is not caused by neglecting these peaks.

It is required that the voltage response be uniform over a range at least broad

Figure 7. Schematic wiring diagram of coupler-comparator

Figure 10. Squared amplification versus frequency for network of resistors and capacitors

enough to include any appreciable response in the network tested. Figure 6 shows the frequency characteristic for this voltmeter, and it is seen to be adequate.

Coupler Comparator

In order to perform the switching necessary without undue confusion, and to couple the output of the network to the voltmeter, a coupler comparator unit is used. The complete schematic diagram is shown in Figure 7. The standard network should match as closely as possible the network being tested, in order to assure maximum accuracy. A set of plug-in standard networks would be highly desirable.

The input to the network is low-impedance and the output is high-impedance. If the network is designed for other terminations, these terminations can be taken into account and proper impedances used when the network is connected to the input and output terminals.

It is possible to use a fiducial mark on the voltmeter and calibrate a potentiometer gain control in the coupler comparator to read the ratios A_{as}^2/A_{cs}^2 and E_{as}^2/E_{ac}^2. It is necessary in that case to be most careful of capacitive loading of the potentiometer to prevent modification of the high-frequency characteristics as gain is changed.

Experimental Results

The experimental work done with this apparatus consists of measuring the bandwidth of several networks directly, and comparing this result with the bandwidth obtained by actually plotting the $A_{(f)}^2$ curve of each network and using the graphical-mechanical method.

Most of the networks measured were simple double-tuned Intermediate-frequency transformers. One transformer of rugged mechanical design was selected as the standard, and its bandwidth was found by the graphical-mechanical method. The $A_{(f)}^2$ curve of this network is shown in Figure 8. Using this standard, several other Intermediate-frequency transformers and one network of resistors and capacitors were measured directly. The $A_{(f)}^2$ curve of each network also was plotted and the bandwidth by the graphical-mechanical method was determined to check on the direct method. Figure 9 shows a typical $A_{(f)}^2$ curve for one of the intermediate-frequency transformers tested. Figure 10 shows the $A_{(f)}^2$ curve and the circuit of a resistance-capacitance filter tested. Table I gives the statistics of these tests and shows that the agreement is very good. No attempt to go beyond two significant figures was made because of the limitations of the equipment at hand.

Conclusions

From the foregoing data it can be seen that the measurement of equivalent bandwidth directly is possible. The percentage difference between the values of bandwidth obtained by this method and by the graphical-mechanical method are quite small.

If this equipment were to be used for routine or versatile measurements of filter bandwidths, certain obvious improvements could be made. The equipment needed, however, is relatively simple and straightforward.

Table I. Comparison of Results of Measurement of Equivalent Bandwidth

Network	f_o, Kilocycles	Bandwidth, Kilocycles Graph*	Bandwidth, Kilocycles Direct
Standard	420	7.6	
Intermediate-frequency transformer A	484	5.8	5.8
Intermediate-frequency transformer B	420	7.6	7.6
Intermediate-frequency transformer C	500	4.8	4.7
Resistance-capacitance network	65	240	220

* By the graphical-mechanical method.

This method could be used for the production testing of filters to check bandwidth within tolerances, or for the laboratory testing of miscellaneous networks of which bandwidth is an important parameter. Refinements of this method may possibly be developed which would make possible the testing, as a 4-terminal network, a complete system, such as a radio receiver or a telephone cable circuit.

No Discussion

A New Electronic Telegraph Regenerative Receiver

B. OSTENDORF, JR.
MEMBER AIEE

Synopsis: An all-electronic device for removing distortion from start-stop teletypewriter signals is described. The circuit utilizes a sine wave oscillator for timing and binary counters for synchronization. It provides low output distortion, high tolerance to input distortion, hit-reduction, transmission of steady-space break signals, and regeneration of one element-length of stop time. It features quick change of speed and code, use of office battery power, and reduction of routine maintenance to one adjustment. Over a year's experience has been obtained with about 100 of these units.

THE growing use of teletypewriter service has brought about an increasing need for regeneration. Operating speeds have tended to become higher, more multibranched long-haul circuits are being used and it has become desirable to allow greater latitude in the maintenance of receivers and other apparatus. These factors cause an increase of signal distortion along the transmission path and a loss of tolerance to distortion at the receiving end of the path. Where the signal distortion is excessive, a regenerative repeater (or even several regenerative repeaters) connected along the circuit may be the best economic answer, and is frequently the only answer to the problem.

Relative to the age of telegraphy itself, the regenerative repeater is a new device. Its use became possible only after the adoption of the printing telegraphy system, and in its first form it utilized the mechanical distributor which also was employed in sending and receiving apparatus. This repeater[1] satisfactorily achieved its major objective; but, with rotating brushes, regular and frequent maintenance is essential to successful operation. To avoid the disadvantages of brush and commutator maintenance, a repeater was developed which used cam-driven contacts for the essential timing of the output signals.[2] The cam-type repeater reduced maintenance time to two or three man hours per month (per 1-way repeater) and has been used widely since 1936.

More recently, at least ten more or less "electronic" regenerative repeaters[3,4,5] have been designed, here and abroad. In each of these, it is the timing circuits which set the style of the complete repeater. The nonmechanical timing methods include resistance-capacitance phase shift oscillators, inductance-capacitance oscillators, free-running and 1-shot multivibrators, gas tube relaxation oscillators, and inductance-capacitance delay networks. All of these methods have been used and each has certain advantages, and possibly disadvantages, as regards economy, stability, size, weight, and maintenance.

The repeater here described is an all-electronic device known as the *143A* regenerative repeater. It was designed specifically to meet the requirements imposed by Bell System teletypewriter service. A number of these repeaters have shown satisfactory performance in commercial service for over a year.

In any semisynchronous or start-stop regenerative repeater, two timing functions are required: character timing and element timing. Character timing synchronizes the receiver by responding to only the initial transition of each coded character. Element timing determines the instant of occurrence for the transitions of the code selecting elements in the reformed output signals.

Paper 50-6, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 2, 1949; made available for printing November 21, 1949.

B. Ostendorf, Jr., is with the Bell Telephone Laboratories, Inc., New York, N. Y.

Principal Circuits

A block diagram of the *143A* regenerative repeater is shown in Figure 1. Element timing in this repeater is generated by a start-stop inductance-capacitance oscillator whose frequency is such that one cycle of sine wave is produced for each element of the code.

Character timing is accomplished by a 3-stage binary-type counting circuit which counts the number of cycles of the oscillation and stops the oscillator when the proper number of cycles has been generated.

Reforming of the output signals is done by a modulating circuit and a flip-flop circuit. The modulating circuit combines voltages from the input signals with impulses from the element timing circuit, and applies impulses selectively to either the left or right grid of the flip-flop circuit which will then follow the sense of the input signals—minus their distortion.

The oscillator is started by the input signal start element. Impulses derived from the sine wave are then applied to the character timing and transmission circuits where the signals are regenerated.

Circuit Description

The details of circuit operation are illustrated by the functional schematic, Figure 2. The general layout is the same as that of the block diagram. Secondary apparatus such as grid bias resistors, by-pass capacitor and vacuum tube heaters are not shown. The voltage wave shapes are approximately those which would be viewed on an oscilloscope, with the letters *A* to *H* indicating points of identical time. This drawing is perhaps best understood by studying the various parts in the following sequence:

Oscillator Control

This is a 2-input circuit which causes the oscillator to start conditionally when

Figure 1. Block diagram of principal circuits—143A regenerative repeater

the input becomes spacing, and holds the oscillator in the running condition after the counting circuits are started.

Inductance-Capacitance Oscillator

To avoid signal distortion, it is necessary that the oscillator start and stop without transients. Transientless starting is effected by applying a direct current through the inductance and approximately zero voltage across the capacitor during the idle period between characters. When the source of this holding current is cut off upon receipt of a start signal, the current in the inductance must then flow into the tuning capacitor. The capacitor then charges sinusoidally. The direct current becomes the peak value of the alternating current and the peak voltage is initially

$E_m = I\sqrt{L/C}$ volts

The voltage peaks of subsequent cycles are kept equal to the peak value of the first cycle by adjusting the feedback energy to just balance the resonant circuit losses. Stopping transients are avoided by stopping at the exact end of a cycle, at which time the alternating current is just equal to, and in the same direction as, the reapplied direct current.

Square Wave Generator

The connection to the modulator circuit is used to supply positive impulses for the selecting or input-sampling function. These impulses (derived through series capacitors) are centered with respect to an undistorted input signal element, and consequently allow a maximum displacement of either end of the element with respect to the start transition.

Modulators

The lower triode is biased so that only the positive impulses which occur during marking elements will be amplified. The upper triode is similarly biased, but it receives inverted input signals so that only the positive impulses which occur during spacing elements will be amplified.

Output Flip-Flop

By its holding action, this circuit converts the transient information contained in the selecting impulses into d-c square waves bearing the information of the input signals and the timing of the locally-generated impulses.

Cathode Follower

This is a power output stage.

Initial Counting Impulse

The same modulator impulse which samples the input start element also is used to generate the first counting impulse. The modulator pulse (dotted line) is amplified by the count recognizer circuit and applied to the first counter (via dotted line) which is caused to flip.

Counting Circuits

When the left triode of a counter circuit flips to the conducting (negative plate) condition, the impulse thus generated flips the succeeding counter in either direction. In the idle condition the three left triodes have positive plates and therefore the action of the initial counting impulse is to flip all the counters in rapid succession. Seven subsequent negative impulses from the square wave generator are required before the idle condition of the three counters again is reached.

Count Recognizer

After transmitting the initial counting impulse, this tube remains cut off as long as one or more of the count voltages is negative. When the three count voltages are again positive (idle condition, time H) the count output voltage applied to the oscillator control circuit will act to stop the oscillator, provided the input signal is marking at the same time. If the input is not marking (as in the case of a stop signal shortened to less than the length of a unit element) the oscillator will not be stopped, but will continue for another 7-cycle count.

Marking Ensuring Circuit

This tube provides a conductive link between input and output during the idle condition. It therefore prevents a spacing output signal in the presence of a steady marking input signal, as might otherwise occur, for example, when power is first applied to the repeater.

Advantages

This repeater affords the following advantages in line with the general requirements:

Low Maintenance

The general rise in maintenance cost per man-hour is well known. This repeater is designed to require negligible routine maintenance for itself, and to permit a reduction in maintenance requirements for all other transmission apparatus, including teletypewriters, in circuits using the repeater.

The regenerator units usually are operated 24 hours per day. Specially designed vacuum tubes and regulated office filament battery provide a tube life measured in years, while the other apparatus represents a good compromise between reliability and first cost. The first use of these repeaters was in an installation of 40 units. Troubles of all kinds during the first year averaged one per four months per repeater and represented a maintenance time improvement of almost six to one over that of the counterpart mechanical regenerative repeaters. Analysis of the trouble reports indicates that no failures have resulted from circuit design inadequacies. Most recurrent failures have been caused by capacitors whose temperature rating was exceeded by the high ambient temperatures which resulted when the maximum number of regenerator units were mounted on a single bay. These troubles have since been eliminated (at a small increase in first cost) by changing to condensers of higher temperature rating.

Only one routine adjustment is necessary to take care of vacuum tube aging: adjustment of the oscillator stop current. All other functions, including tuning, are independent of tube characteristics during the life of the tube. Tuning and oscillator feedback are factory adjustments.

Compactness

Because of the increased number of regenerated telegraph circuits, required floor space and weight of the repeater are important. The circuit is fully electronic and uses miniature tubes, pigtail resistors, and so forth. This, together with the simple timing device, enables 34 1-way regenerator units to be accommodated in a standard $11^1/_2$-foot 19-inch relay rack bay. Each unit weighs 13 pounds. A single unit is shown in Figure 3.

Tolerance to Distortion

The width of an element sampling impulse is less than one per cent of the width of a signal element. (All percentages are in terms of a whole element.) The impulses are timed to be in the exact center of an undistorted incoming signal element; accordingly any transition of the input signals may be displaced up to $49^1/_2$ per cent without causing an error. Tuning inaccuracies reduce this tolerance but experience indicates that 45 per cent is a reliable minimum under field conditions.

Stability

Over a range of 55 degrees Fahrenheit, temperature compensation of the tuning capacity keeps the maximum output distortion under 2 per cent in most cases (4 per cent, in one case out of six). Over a period of one or two years, an additional drift of not more than 3 per cent distortion, or one-half per cent frequency error, caused by aging of the coil and capacitor, is anticipated. The aging error can be removed at any time by an adjustment of the capacity and the temperature error can be removed by allowing a warm-up time before adjustment. This degree of stability is obtained without resort to expensive tuning components.

Use of Office Battery Power

Power supply of +130, −130, and −24 volts is used for the repeater. These voltages are available from power plants having battery reserve which are normally provided in offices where the repeater will be used. Use of the office battery power rather than rectified commercial alternating-current avoids service interruptions which would result from failure of the commercial a-c supply.

Rapid Change of Operating Speed

Speed is controlled by a switch which selects a preadjusted tuning capacity for each desired speed. The possibility of a rapid change in speed permits a reduction in the number of spare repeaters which must be maintained in an office handling more than one speed. Three speeds—60, 75, and 100 words per minute—are provided by this unit.

Rapid Change Between Five and Six Unit Selecting Code

As described the character timing circuit operates with a code having five selecting elements. In order to function with teletypesetter code, which has six selecting elements, a resistance-capacitance timing and clamper circuit (one twin-triode, not shown) can be added to eliminate one of the counting impulses. In this way one extra cycle of sine wave will be generated before the counting circuit comes to a stop. When the additional circuit components are provided, switching between five and six unit code is done simply by removing or inserting associated vacuum tube. No adjustment is necessary.

Reduction of Line Hits

In 2-condition signaling such as telegraphy, sporadic changes in condition

Figure 2. Functional schematic—*143A* regenerative repeater

during a mark or space signal are called hits. A regenerative repeater will eliminate hits which do not occur during the sampling impulse with the following important exception: A spacing hit during a stop element or idle period will act the same as an incoming start signal. Unless the hit is extremely short, it will cause the repeater to begin its cycle of operation. This is actually the worst sort of hit since it may put a start-stop system out of synchronism for many characters, particularly if the signals go through several pieces of start-stop synchronized apparatus. Electronic regenerative repeaters tend to be very susceptible to this trouble because of their rapidity of response. One type of mechanical regenerator which now is being used requires about two milliseconds to unlatch, whereas an electronic trigger device ordinarily will act in a few microseconds.

This repeater eliminates most of the susceptibility to false unlatching by not starting the synchronizing action of the character timing circuit until one-half element after the beginning of a code character—that is, at the time of selection of the start pulse. The effect is then that a hit of less than 11 milliseconds (one-half element at a speed of 60 words per minute) will not unlatch the repeater. The sine wave oscillator will begin a cycle but will return to steady state soon after the end of the hit.

Steady Space or Mark

When a steady mark is being received, the same conditions which stop the oscillator also actuate a circuit which is paralleled with the output circuit and insures a marking output signal. This avoids complete dependence upon the holding action of the output flip-flop tube, and is required for a number of minor reasons not covered here.

When a steady space is being received, the oscillator never stops and the mark-restoring circuit just mentioned is never actuated. Accordingly, a series of uninterrupted spacing selections is made. Retransmission of an uninterrupted space is valuable when break circuits or timing circuits are connected on the line, or when manual Morse signals must go through the repeater.

Partial Regeneration of the Stop Element

Because of its indefinite length, the stop element of a start-stop signal cannot be regenerated; or, more accurately, the interval between two start transitions—that is, character length—cannot be regenerated. Even with automatic signals where the characters are all of the same length, the stop element cannot be regenerated in the true sense, because there must be some amount of time provided, however small, for the regenerator to come to rest in order for it to operate on a start-stop basis and permit some variation in the speed of the teletypewriter transmitters.

Since it is not regenerated, the stop element may suffer cumulative distortions, especially in circuits having more than one regenerated section in tandem. Transmission circuits having long time constants, speed errors, and fortuitous effects contribute to changing the character length, with a consequent fortuitous lengthening or shortening of succeeding stop elements. Properly, a regenerative repeater should limit the shortness of a stop element being retransmitted, to prevent cumulative shortening to the point of failure.

This limiting action is best applied when the code system used has a stop period longer than the other elements. In this case the repeater regenerates the first element length of stop period in the same way as any other element is regenerated. When a foreshortened stop pulse is received, the timing oscillator does not stop but, after causing selection of a 1-element stop period, proceeds with timing of the next character. Recycling of the character timing circuit is not affected by the failure to stop, since character timing is merely a matter of counting the proper number of cycles for the second character after finishing the count of the first.

Figure 3. *143A* regenerative repeater

System Application

The regenerative repeater being discussed was designed concurrently with a new hub-type method of multibranch operation. The repeater itself is simply a 1-way device, but when incorporated with the new hub transmission system, each branch or spoke (one at a time) may send through the single 1-way regenerator unit to all the other stations, thereby making efficient use of the regenerator. The hub-coupling circuits, one of which is associated with each branch, are voltage-operated devices and may be driven directly from the output of a vacuum tube circuit; consequently neither input nor output relays are required in the regenerative repeater. An additional saving in first cost, maintenance, and space results

5. An Electronic Regenerative Repeater for 7/2 Unit Start-Stop Telegraph Signals, R. O. Carter, L. K. Wheeler, A. C. Frost. *Journal*, Post Office Electrical Engineers (London, England), January 1949, page 222.

Discussion

Harold J. McCreary (Automatic Electric Company, Chicago, Ill.): Some years ago at the laboratories of the Automatic Electric Company in Chicago we did some work along this line, but it specifically applied to the correction of dial pulses on long farm lines with 10 or 12 parties.

We found that the greatest rate of change occurred at the instant dial contacts were made or broken, and that using this fact rather than the magnitude of current to operate a repeater, the dial pulses could be perfectly reproduced in spite of extreme distortions of the incoming dial pulses. We received a patent which describes this work in some detail.[1]

B. Ostendorf, Jr.: If signal distortion is systematic (comprising only bias and characteristic distortion) and is constant, it may be removed by designing the combination of line and terminal equipment to have the desired variation of loss and phase with frequency. This is called equalization. Adding a derivative, as described by Mr. McCreary, is one method of equalization which will reduce bias and negative characteristic distortion (systematic shortening of shorter elements, either marking or spacing, in a train of coded signals).

Where the distortion is variable or includes a fortuitous component such as is caused by interference, signal perfection can be restored only by regeneration. Regeneration provides a more general treatment for distortion: foreknowledge of the type and amount of distortion is not required.

Combined Phase and Ground Distance Relaying

WARREN C. NEW
ASSOCIATE AIEE

A NEW relaying system is described herein providing complete phase and ground distance relaying protection for transmission lines, which features a reduction in the necessary equipment over the 6 directional-reactance-distance relay system usually applied where three relays are connected to protect against 3-phase, phase-to-phase, and double-phase-to-ground faults, and three relays are connected to protect against single-phase-to-ground faults. The reduction in equipment is achieved by causing the directional element of the ground-reactance relay to perform the double duty of detecting faults of a phase nature as well as faults of a ground nature. This new system also offers the advantage of providing complete phase and ground protection without the use of objectionable switching arrangements heretofore used to select the faulted-phase current or potential.

The combined system is effected by adding to the basic directional-reactance-distance relay for ground fault protection a reactance relay which operates with the directional-fault-detecting element of the ground relay to provide the phase-fault protection.

Description

The basic directional-reactance-distance relay for ground-fault protection is composed of a directional-impedance starting unit having a circular impedance characteristic which passes through the origin on an R and X diagram, an ohm unit having a pure reactance characteristic, and a transfer relay to change the ohm unit calibration, thus providing a second zone in ohmic reach. The added reactance relay includes an ohm unit having a reactance characteristic, and a transfer relay for changing its calibration. Since the directional-impedance starting unit of the ground relay will respond to all faults within its zone of reach, it can be used in conjunction with the phase ohm units to provide phase-fault protection as well as with the ground ohm units providing ground-fault protection.

The complete relaying system for the combined phase-and-ground protection of 3-phase transmission lines includes three directional-reactance-distance relays, one per phase, for the ground relaying; and three reactance relays, one per phase, for the phase relaying; two timing relays, one each for the phase and ground relaying; an auxiliary relay for blocking the ground trip circuits; and an auxiliary current transformer.

The timer is described completely in an AIEE paper.[1] Both timers are started by the impedance starting units of the ground relays when a fault occurs and they control the tripping time in accordance with the operation of the phase and ground ohm units. Two timers are provided so that proper time co-ordination can be made with other portions of the system, especially where different times of tripping are required for phase faults compared to ground faults.

The auxiliary blocking relay consists of three telephone relays which are used to prevent the ground ohm units from tripping on all except single-phase-to-ground faults. One blocking telephone relay is associated with each phase.

The auxiliary current transformer is used to compensate for the mutual effect of the ground current and also for the current in neighboring or parallel lines. This current compensation is effected by supplying the relays with enough of the residual current of the protected line and of any nearby or parallel lines to offset the extra potential caused by the mutual effect of the ground current and neighboring line current.

In certain cases, some variation in ground distance measurement is introduced by arc resistance especially where there is an appreciable phase angle difference between the generated potentials behind the two ends of the line. This variation would not lead to incorrect operation with normal settings using the current compensation described above. Potential compensation might be used to correct the error resulting from out-of-phase generated potentials, but also it introduces a similar error which may cause just as much variation in measurement. This error is produced by the phase angle difference between the zero sequence current supplied from the relay end of the system (I_0') and the total zero sequence current in the fault (I_0). For example, if the fault occurs near a transformer having a grounded neutral, I_0 may be considerably more lagging than I_0' which may pass through considerable line and ground resistance, hence the error may be quite large.

Choice of Potential versus Current Compensation

The problem of potential versus current compensation has long been considered in the application of ground distance relays. In measuring the distance to a single-phase-to-ground fault, two approaches may be considered: the actual measurement of the zero sequence impedance by separating it from the positive and negative sequence impedances through the use of filters or other

Figure 1. Current and potential connections to the relay using current compensation

separating circuits; or the measurement of phase quantities with residual or zero sequence quantities added to correct for the effects of induction, double end feed, and so forth. Voltage compensation lends itself particularly well to the first approach, while current compensation lends itself to the second approach.

The use of zero sequence quantities alone through potential compensation has the disadvantage of requiring the relay to operate on very small quantities so that the torque produced is very small. Such a relay is beset by various ills induced by its extreme sensitivity, such as transient operation, contact rebound, and so forth. The voltage restraint applied to the relay is little more than half the line-to-neutral voltage since the potential compensation is applied to reduce the phase-to-neutral voltage. Voltage compensation is most useful where there is a large amount of reactive current transfer over the protected line section or where the phase angle difference between the generated potentials behind the two ends of the line section is large. Potential compensation has been described completely elsewhere.[2]

The use of phase quantities with zero sequence correction through current compensation offers the advantage of a higher torque relay. The potential restraint applied here is the full line-to-neutral voltage. Special precautions must be taken, however, to insure that all the necessary corrections are made.

Applied Compensation

To use a high-torque relay, the method of current compensation was selected for this relaying system. This current compensation corrects the phase quantities applied to the relay for the effects of mutual induction between the line and ground and between two lines which are mutually coupled. The complete derivation of the mathematical equations are shown in Appendix I.

The resulting current (I_R) and potential (V_R) applied to the relay are as follows, where the primed values represent line quantities of the protected section towards the fault, I_0'' is the zero sequence current and Z_m the mutual impedance coefficient of a parallel line, I_{res}' is the residual current of the protected line, I_{res}'' is the residual current of the parallel line, and I_aR_a is the voltage drop due to the arc.

$$V_R = I'Z_1' + I_0'(Z_0' - Z_1') + I_0''Z_m + I_aR_a$$

which is the phase-to-neutral voltage of the line.

$$I_R = I' + K'I_{res}' + K''I_{res}''$$

The quantities K' and K'' are explained in Appendix I. Figure 1 shows schematically how these quantities are supplied to the relays.

The relay therefore measures the positive phase sequence impedance of the protected line section, Z_1', plus an error term. A reactance relay will only be affected by the reactance or j component of this error term. The error term is

$$\frac{3R_a}{2\dfrac{I_1'}{I_1} + \dfrac{I_0'}{I_0}\dfrac{Z_0'}{Z_1'} + \dfrac{I_0''}{I_0}\dfrac{Z_m}{Z_1'}}$$

where

R_a = the resistance of the arc.

Neglecting the effect of mutual induction, the error term can be expressed as

$$\frac{3R_a}{2\dfrac{Z_1}{Z_{1R}} + \dfrac{Z_0'}{Z_1'}\dfrac{Z_0}{Z_{0R}}}$$

where

Z_{1R} and Z_{0R} = the sequence impedances on the relay side of the fault.

If the denominator of this latter error impedance term is real, there will be no error. Many lines approach this condition if the neutrals are solidly grounded since the various impedances are of approximately the same power factor and on short lines the phase angle between the generation at the two ends of the line will be small. Similarly if the two neutrals are both grounded through fairly large and equal resistances, the error will also be small.

Overreach will be more likely to occur when

1. The generation on the relay side of the fault is leading the generation on the far side of the fault (I_1' leads I_1).

2. The impedances on the relay side of the fault, either positive or zero sequence, are leading the impedances on the far side of

Figure 2. Test arrangement to determine errors resulting from arc resistance, earth resistance, and load current

Figure 3. Effect of arc resistance with double-end-feed and various neutral grounding resistances (Case A)

Figure 4. Effect of earth resistance with double-end-feed and various neutral grounding resistances (Case A)

Figure 5. Effect of arc resistance with double-end-feed and various neutral grounding resistances (Case B)

the fault (Z_{1R} leads Z_1, or Z_{0R} leads Z_0).

3. The zero sequence impedance of the protected line is more lagging than the positive sequence impedance (Z_1' leads Z_0').

4. The zero sequence current of a parallel line is more lagging than the zero sequence current of the protected line (I_0 leads I_0'').

5. The mutual impedance of a parallel line is more lagging than the positive sequence impedance of the protected line (Z_1' leads Z_m).

Since tripping of the ground ohm units on all except single-phase-to-ground faults is prevented by the auxiliary blocking relay, the errors resulting from 3-phase, phase-to-phase, and double-phase-to-ground faults need not be considered here. These faults are all cleared by the operation of the phase ohm units. Figures 2, 3, 4, 5, and 6 show the magnitude of the errors under various conditions of arc resistance, earth resistance, and neutral grounding resistance for single-phase-to-ground faults.

Figure 2 shows the nature of the test

Figure 6. Effect of earth resistance with double-end-feed and various neutral grounding resistances (Case B)

setup using an artificial transmission line that was used to determine the curves of Figures 3, 4, 5, and 6 illustrating the nature and magnitude of the error resulting from various conditions of arc resistance, earth resistance, neutral grounding resistance and load current during single-phase-to-ground faults. The first of the two numbers indicated on each curve is the neutral grounding resistance in ohms at the relay end of the system, and the second figure the opposite end. The broken line curves represent conditions where load current is flowing in addition to relay fault current. In Case *A* the load current used was 125 per cent of the relay fault current, and in Case *B* the load current was 50 per cent of the fault current. Figures 3 and 4 are for Case *A* and Figures 5 and 6 are for Case *B*. Values above the nominal value on each curve represent overreaching. Overreaching is the increase of the relay reach beyond its calculated value so that the relay tends to trip for faults within a longer part of the protected line.

Starting Unit

In this phase and ground distance relaying scheme a unit must be provided to determine first, that fault conditions actually exist and second, to determine if the fault is in the tripping direction. These functions are performed by the directional-impedance starting unit of the basic reactance-distance relay.

The starting unit is a 4-pole induction cup unit. The side poles are energized by the quadrature voltage to produce the polarizing flux. The back pole is energized by the phase-to-neutral voltage of the protected phase to produce the restraining flux. The front pole is energized by the line current of the protected phase to produce a directional torque dependent upon the phase angle between the current and the polarizing voltage. Figure 7 shows the schematic connections for the starting unit.

The starting unit will pick up when the restraining torque equals the operating torque. The equation for this condition is

$$TE_AE_{BC}\sin\beta = 550I_AE_{BC}\cos(\alpha - 30 \text{ degrees})$$

where T is the voltage restraint tap setting, β is the angle by which E_A leads E_{BC}, and α is the angle by which the current I_A leads the quadrature voltage E_{BC}.

For a 3-phase fault, $\beta = 90$ degrees, and $\alpha = (90 \text{ degrees} - \phi)$ where ϕ is the phase angle of the line. The relay will then

Figure 7. Schematic connection of the directional-impedance starting unit

pick up when the current is equal to

$$\frac{TE_A}{550\cos(60 \text{ degrees} - \phi)}$$

With a 100 per cent tap setting and a voltage E_A of $115/\sqrt{3} = 66.4$ volts, the pickup current will be 12 amperes at a phase angle of 60-degree lag. Typical variation of pickup current with phase angle and tap setting is shown in Figure 8. Pickup currents for other types of faults can all be determined from the basic equation shown above.

Normally, the setting of the starting unit is not required to be particularly accurate and it is sufficient to assume for all faults that with 115 volts phase-to-phase at its terminals and tap settings of 100 per cent, the relay will have a mini-

Figure 8. Typical current pick-up characteristics of the directional-impedance starting unit (current values apply to 3-phase faults)

Figure 9. Schematic connections of the ground and phase ohm measuring units

mum pickup of 12 amperes at the maximum torque angle of 60-degree lag. The operating or directional torque closes the relay contacts when the fault current is in the tripping direction and of a sufficient magnitude to overcome the voltage-restraining torque. The operating torque on 3-phase faults is a maximum for fault currents lagging by 60 degrees, and is reliable down to one per cent voltage with secondary current from 5 to 60 amperes. The voltage restraining torque is a maximum under balanced 3-phase conditions which exist normally and during power swings when operation would be undesirable.

The starting unit causes tripping in third-zone time for all types of faults. Since the line currents are different for phase-to-phase faults compared to single-phase-to-ground and 3-phase faults, the reach of this unit will be shorter for phase-to-phase faults by a factor of approximately 15 per cent. Also on phase-to-phase faults, a 30-degree shift of the directional-impedance characteristic on an R and X impedance diagram may be expected when there is no collapse of the voltage triangle. When there is a complete collapse of the voltage triangle on a phase-to-phase fault, there is no shift of the relay characteristic. This subject is discussed in greater detail in Appendix II.

Ohm Units

Once it has been determined that a fault condition actually exists, a unit must be provided to measure accurately the distance to that fault and decide whether or not the fault lies within the tripping zone. This function is performed by the ohm units which are reactance measuring units.

The ohm units of both the ground relays and the phase relays are 4-pole induction cup units. The front and back poles each have two current coils which produce a polarizing flux proportional to the sum of currents supplied to them. The right-hand pole has two current coils to produce the operating flux which is also proportional to the sum of the two currents supplied. The flux in the right-hand pole is made to lag its current by about 90 degrees by means of a phase-shifting winding.

The left-hand pole has a potential coil which produces the restraining flux. The schematic connections for the phase and ground ohm units are shown in Figure 9. The operating theory and torque equations for these units are explained in a previous paper.[1]

The ground ohm units are supplied with a phase current in one current winding and the compensating current from the auxiliary current transformer in the other current winding. The left-hand or restraint pole is supplied with the phase-to-neutral voltage through a tapped autotransformer which allows adjustment of the restraint in one per cent steps.

The phase ohm units are supplied with two phase currents, one in each current winding. The left-hand or restraint pole is supplied with the phase-to-phase voltage between the two phase currents supplied to the current windings. This voltage is supplied through a tapped autotransformer which also allows adjustment of the restraint in one per cent steps.

The phase and ground ohm units will measure the same reactance within ±2 per cent over a range of 2 to 40 amperes secondary current with any power factor obtainable on a transmission line. The minimum voltage during fault conditions imposes no practical limitations on the accuracy of the ohm unit. Measurements are accurate within ±2 per cent down to 1 volt for a one-half ohm phase-to-neutral measuring unit.

Ohm Unit Transfer Auxiliary

The ground and phase ohm units are each provided with a telephone relay known as the ohm unit transfer auxiliary (OX). This transfer relay provides the second step of transmission line protection by means of a switching arrangement which changes the amount of voltage restraint supplied to the ohm units. The operation of this transfer auxiliary is controlled by the second time zone contacts of the timer. The normally closed contacts of the transfer auxiliary provide the voltage restraint for the instantaneous or first zone of the transmission line protection.

If the fault is beyond the first zone of protection, the transfer auxiliary relay switches to the Number 2 taps on the autotransformer, thus supplying a smaller restraint potential to the ohm unit and extending the ohm unit reach. The extended ohm unit reach then constitutes the second zone of the transmission line protection.

Auxiliary Blocking Relay

The auxiliary blocking relay contains three telephone relays, A_A, A_B, and A_C, which are used to prevent the ground ohm units from tripping on all except single-phase-to-ground faults. One blocking telephone relay is associated with each phase. The contacts of the telephone relays are arranged in the trip circuits so that they may be used to provide this tripping selection.

This arrangement provides 3-step protection on single-phase-to-ground faults. This is accomplished by connecting a normally open contact of the protected phase-blocking relay in series with a normally closed contact from each of the other two phase-blocking relays. Blocking is then accomplished for all faults except single-phase-to-ground faults. Figure 10 shows this arrangement of contacts in phase A of the trip circuits. It can be seen that tripping will be blocked when two or more phases are involved in a particular fault.

When the auxiliary blocking relays are connected so as to block the tripping of the ground ohm units on all except bona-fide single-phase-to-ground faults, some thought must be given to the possibility of operating more than one of the starting units on such a fault. Such a possibility is very remote as will be shown. In a recent AIEE paper,[3] a method of calculating the performance of distance relays shows that for a single-phase-to-ground fault, the lagging-phase starting unit will operate falsely only on a nearby fault having a fairly high fault resistance. This is shown in Figure 11. This combination of circumstances is not likely to happen, particularly when the relay is

Figure 10. Blocking relay contact arrangement for phase A

Figure 11. Impedance seen by ground relays during a phase *A*-to-ground fault

located close to a generating source. Such a fault, however, most likely will be cleared by the phase relays since the impedance will fall into their tripping zone as is shown by Figure 12.

Operation of the D-C Control Circuits

Referring to the elementary connection diagram in Figure 13, the sequence of operation of the d-c control circuits may be explained. A single-phase-to-ground fault on phase *A* will operate the starting unit *SU* which will in turn operate the auxiliary blocking relay A_A and start the timing unit *TU* through its auxiliary relay *TX*. The trip circuit for phase *A* will then be complete up to the ground-ohm-unit contacts O_ϕ. If the fault is within the first zone of reach of the ground ohm unit, that unit of course will operate and trip the circuit breaker through the first zone ground targets T_{1G}. If the fault is

Figure 13. Circuit breaker control circuits for phase *A*

beyond the first zone reach, after the timer has operated the *TU*2 contacts, the ohm unit transfer auxiliary will operate and change the ohm unit calibration by applying a smaller potential restraint. If the fault lies within the second zone of reach, the ohm unit will operate and trip the circuit breaker through the second zone ground target T_{2G}. If the fault is beyond the second zone reach, then when the timer has operated its TU_ϕ contact, the circuit breaker will be tripped by the starting unit contact *SU* through the third zone target T_ϕ.

The phase ohm units operate in much the same manner as the ground ohm units, since they work in conjunction with a separate auxiliary transfer relay and separate timer. The difference is the a-c connections of the phase ohm units allowing them to operate on different line quantities.

A separate timer is provided for the phase trip circuits as well as the ground trip circuits so as to provide close time selectivity with the relaying on other portions of the system. It is especially useful where different times of operation of phase and ground relays on other portions of the system are desired. If such close selectivity is not required, only one timer would be necessary. The choice of one timer has the disadvantage of requiring a different interpretation of the available targets to determine the type of fault that caused the circuit breaker trip-out.

Conclusions

A relaying scheme is described for providing high-speed distance relaying and back-up protection against ground faults, so combined with high-speed distance relaying and back-up protection against phase faults that a minimum of relays are used. Current compensation is applied requiring the minimum of auxiliary equipment with the least adjustment.

Appendix I

The distance relay being used to measure single-phase-to-ground faults is supplied with phase-to-neutral voltage. The left part of Figure 14 shows the distribution of sequence currents and potentials on a typical system under single-phase-to-ground fault conditions. This figure does not take into consideration the phase angle of the various voltage drops at the fault, but simply uses these drops as scalar quantities. The actual vector diagram of such a fault condition would be as shown to the right of Figure 14, where it is seen how the various drops may be projected on the phase-to-neutral generated voltage, E_g. Referring to Figure 14, the phase-to-neutral voltage is V_R and is equal to

$$= I_1'Z_1' + I_1'Z_s' + I_1'Z_s' + I_0'Z_m + I_aR_a$$

where quantities with the subscripts 1, 2, and 0 are the positive, negative, and zero

Figure 12. Impedance seen by phase relays during a phase *A*-to-ground fault ($Z_{BC}' = \infty$)

Figure 14. Distribution and phase relations of sequence potentials during a single-phase-to-ground fault (for the faulted phase only)

sequence quantities, respectively; primed values represent quantities of the protected line section. I_0'' is the zero sequence current in a parallel line which has a mutual coupling with the protected line and Z_m is the zero sequence mutual coupling coefficient of such a parallel line. I_aR_a is the voltage drop due to the arc.

In order to use phase quantities, these must be separated and since we usually assume that $Z_1' = Z_2'$ we may substitute

$$V_R = I_1'Z_1' + I_2'Z_2' + I_0'Z_0' - I_a'Z_1' + I_0'Z_0' + I_0''Z_m + I_aR_a$$
$$= I'Z_1' + I_0'(Z_0' - Z_1') + I_0''Z_m + I_aR_a$$

Dividing this voltage by Z_1' gives the current necessary to measure Z_1' in a distance relay having a phase-to-neutral voltage restraint.

$$I = I' + I_0'\left[\frac{Z_0' - Z_1'}{Z_1'}\right] + I_0''\frac{Z_m}{Z_1'} + \frac{I_aR_a}{Z_1'} \text{ or}$$
$$= I' + K'I_{res}' + K''I_{res}'' + \frac{I_aR_a}{Z_1'}$$

where I_{res}' and I_{res}'' are the residual currents of the protected line and parallel line, respectively, and

$$K' = \frac{Z_0' - Z_1'}{3Z_1'} \text{ and } K'' = \frac{Z_m}{3Z_1'}$$

Since the actual arc current cannot be measured, the relay is supplied with the phase current, a portion K' of the residual current of the protected line, and a portion K'' of the residual current of a parallel line. The impedance seen by the relay with this current and the phase-to-neutral voltage will then be

$$Z \text{ relay} = \frac{[I'Z_1' + I_0'(Z_0' - Z_1') + I_0''Z_m + I_aR_a]Z_1'}{I'Z_1' + I_0'(Z_0' - Z_1') + I_0''Z_m}$$
$$= Z_1' + \frac{I_aR_aZ_1'}{I'Z_1' + I_0'(Z_0' - Z_1') + I_0''Z_m}$$
$$= Z_1' + \frac{I_aR_aZ_1'}{(I_1' + I_1' + I_0' - I_0')Z_1' + I_0'Z_0' + I_0''Z_m}$$

Since $I_a = 3I_0 = 3I_1$ at the fault and $I_1' \approx I_1'$ we may substitute

$$= Z_1' + \frac{3I_1R_aZ_1'}{2I_1'Z_1' + I_0'Z_0' + I_0''Z_m}$$

Dividing numerator and denominator by I_1Z_1'

$$= Z_1' + \frac{3R_a}{2\frac{I_1'}{I_1} + \frac{I_0'}{I_0}\frac{Z_0'}{Z_1'} + \frac{I_0''}{I_0}\frac{Z_m}{Z_p}}$$

Figure 15. Phase relations of currents and potentials supplied to the phase-A starting unit

The second term of this equation then is the impedance error resulting from a single-phase-to-ground fault as seen by the relay. In the case of the reactance relay, the error becomes the j component of the error impedance.

With short lines or heavily interconnected systems, the phase angle difference between the currents supplied to the fault from the relay end of the system (I_1', I_0') and the total fault currents (I_1, I_0) will be small and these currents will be inversely proportional to the system impedances. The ratio

$$C = \frac{I_1'}{I_1} = \frac{Z_1}{Z_{1R}}$$

can then be used to express the impedance error in other terms.

Similarly

$$C_0 = \frac{I_0'}{I_0} = \frac{Z_0}{Z_{0R}}$$

where Z_{1R} and Z_{0R} are the sequence impedances on the relay side of the fault.

Neglecting the effect of mutual induction, the error then becomes:

$$\text{error} = j \text{ component of } \frac{3R_a}{2\frac{Z_1}{Z_{1R}} + \frac{Z_0'}{Z_1'}\frac{Z_0}{Z_{0R}}}$$

The effects of this error impedance are discussed at length in the body of the paper.

Appendix II

As described previously in the text of this paper and as shown by Figure 7, the directional-impedance starting units are supplied with a line current for operating, phase-to-neutral voltage for restraining, and the quadrature voltage for polarizing. The angle of maximum torque, or the angle of minimum pickup of the unit is controlled by the angle between the operating current and the polarizing voltage. This angle is set within the relay at 30 degrees current leading voltage. Figure 15 shows the phase relations of these currents and potentials under unfaulted conditions and again under phase-to-phase fault condition. This diagram shows that for an assumed line impedance angle of 60 degrees lag, there is no shift between the line current and the quadrature voltage under either three-phase or single-phase-to-ground fault conditions. Under phase-to-phase fault conditions, however, there is a 30 degree shift of the characteristic possible, provided there is no collapse of the voltage triangle. This shift is caused by the new relative position of the fault current with respect to the polarizing voltage. The phase-to-phase fault current will lag the phase-to-phase voltage causing its flow by the line impedance angle or 60 degrees lag as assumed previously. This factor requires that to achieve the maximum torque angle position, the line impedance angle would have to be 90 degrees lag. Thus the relay characteristic is shifted to 90 degrees lag. As the voltage triangle collapses under the phase-to-phase fault, the shift of the characteristic becomes smaller until at complete collapse, the characteristic returns to its original position.

There also is a small change in the reach of the directional-impedance starting units under different fault conditions. During 3-phase and single-phase-to-ground fault conditions, there is available a phase-to-neutral voltage to cause a certain line current to flow through the line impedance of a single conductor. During phase-to-phase fault conditions there is available a phase-to-phase voltage to cause a certain line current to flow through twice the line impedance of a single conductor. It is obvious that the line current will not be the same for the two conditions, the phase-to-phase fault conditions producing about 85 per cent of the former current. A smaller current indicates a larger impedance and this has the effect of reducing the reach of the starting unit on phase-to-phase faults by a factor of 15 per cent.

Discussion

C. A. Streifus and **Frank von Roeschlaub** (Ebasco Services Incorporated, New York, N. Y.): Mr. New presents in a complete and concise form the description of and technical background applying to this combination of phase and ground distance relaying without carrier. This appears to require a minimum of equipment but at the same time provides most of the characteristics required for fast directional phase and ground relaying of short and medium length transmission lines carrying relatively small quantities of power either for line-fault operation or during transient swing conditions.

While Figure 13 of the paper indicates that circuits are for circuit breaker control fo phase A, we assume that equivalent trip ping and timing circuits for phases B and C are connected between the positive lead and the auxiliary switch in parallel with phase A tripping circuits.

In Figures 11 and 12, it appears that this combination of relays does not provide third

zone backup protection for faults occurring in the direction opposite to that in which the relays are pointed. This region, however, is covered by the second or third zone of similar relays at the opposite terminal of the line section under protection.

Figures 11 and 12 indicate further that the characteristic impedance of the reactance and starting units for both phase and ground relays adequately cover the fault zone areas for phase and ground faults for relatively short lines carrying small amounts of power. Because of the breadth of the starting unit circle in a direction perpendicular to the line impedance characteristic on the conventional *R-X* diagram, if the relays are applied on long lines or on short lines near the electrical center between systems, there may be false tripping during some transient swing conditions when large quantities of power are flowing and especially for the condition when this power is in a direction opposite to that in which the relays are pointed. This combination of conditions, however, is rare.

Although not mentioned in the paper, problems associated with distance relaying on a 3-terminal line exist similarly in the application of these relays, namely, sequential clearing of circuit breakers is required and impedance viewed by a certain relay on a 3-terliminal line may be relatively high during a fault condition because of the fault current supplied from the third terminal.

S. L. Goldsborough (Westinghouse Electric Corporation, Newark, N. J.): The combined phase and ground relaying combination described by Mr. New does not seem to offer anything new in the way of phase relaying or ground relaying. Apparently the only new feature is the combination whereby one starter element per phase is required to function on both phase faults and ground faults.

In regard to the phase relaying it is noted that the distance measuring element now is supervised by a starter element which was discarded several years ago. It is recalled that several years ago the reactance phase relay employed a modified impedance supervising element which was energized by fault current and both faulted and unfaulted phase voltages.

This type of starter element was later abandoned in favor of an element energized only on fault current and voltage apparently in order to overcome some inherent difficulties. In view of this it would seem that the return to the former type of starter element in the new combination is a step backwards.

In considering the ground relaying a number of interesting points come up. In employing the current compensation method it is to be noted that nothing new has been obtained over and above what has been available for approximately the last 15 years. A reactance ground relay utilizing current compensation has been on the market for this length of time but its application has been very limited because of fundamental troubles occasioned by the starter element operating on line current. Nothing has been done in the described combination to overcome the fundamental limitations of current compensation other than the rather drastic reduction in the "reach" of starter element which, of course, seriously limits the ability of the measuring elements to accommodate fault resistance and provide backup protection.

In discussing the advantages and disadvantages of the potential versus the current method of compensation the author makes a rather puzzling statement. He states that, because part of the line to neutral voltage is discarded in the voltage compensation method, the remaining voltage is not sufficient to operate a relay with adequate torque. This might be true if three ground relays were used and their potential coils were energized continuously on the normal line to ground voltage. This is possibly what Mr. New has in mind in bringing up this point. However, the use of three normally energized relays would certainly not be an efficient way of employing voltage compensation. The use of zero sequence quantities in voltage compensation naturally suggests the use of one reactance measuring element with a phase selector in the potential circuits. With a potential switching device it is, of course, not necessary nor desirable to leave the potential circuits energized continuously and, therefore, it is obvious that the amount of line to ground voltage is immaterial. A normal and desirable energy level can be maintained in a relay regardless of the value of input voltage as long as the relay does not have to withstand a higher continuous voltage. Such a relay was described in October 1948 before the Institute[1] and it is, therefore, difficult to conceive of any engineering reason why the author has brought up the point.

The author points out that current compensation is subject to error where there is a phase angle difference between the generated potentials behind the two ends of the lines. It is claimed that this error would normally be inconsequential. It also is pointed out that voltage compensation avoids this particular error but introduces another error which may be just as large. It would seem that this is not a fair comparison of current and voltage compensation since it implies that current compensation is subject to only one error and voltage compensation is subject to another equally deleterious error. This is not at all the case, as would be apparent, if the author also had given the equation covering voltage compensation. Voltage compensation is subject to one error, because of the difference in phase angle of the zero sequence impedances on both sides of the fault, whereas current compensation is subject not only to the above error but in addition is subject to four other errors. An examination of the equations 23 and 25 of the Lewis and Tippett paper[2] will make it quite evident that where mutual inductance is involved the current compensation method is subject to five errors whereas voltage compensation is subject to only one error. Indeed the author later on in his discussion brings out this point when he lists the conditions under which the reactance element is liable to overreach.

It is felt that the chief impediment to the general successful use of combined phase and ground relaying is the fact that, in order to prevent false operation on single-phase-to-ground faults where there is flow of fault current on all three phases, the reach of the starter must be drastically restricted. It is noted that all the diagrams given show the starter element circle reaching approximately only twice as far as the instantaneous zone. This certainly does not allow the first zone element to accommodate much arc resistance. This limitation applies even more to the second element since the diagrams clearly show that a normal second element setting of twice the first zone setting could not be attained even if fault resistance were zero. On the same basis it is evident that a suitable backup setting for the third zone is impossible.

It also should be noted that the starter element is an uncompensated element and is, therefore, subject to all the errors in distance measurement which must be removed from the distance measuring elements. In other words, even if we assume no fault resistance whatever, it would be impossible to depend on correct relay operation when set according to the diagrams shown.

A further point is that, by combining the phase and ground starter elements, the restrictions dictated by ground fault conditions also are placed on the phase relays thus impairing the flexibility of phase distance relaying.

In view of the foregoing points it seems evident that the elimination of one starter element per phase in the combined phase and ground relay equipment described is hardly worthwhile.

C. W. Frederickson (Commonwealth Services Inc., Jackson, Mich.): The use of distance ground relays has been rather limited in the past, no doubt due largely to the complexity of the numerous elements and the resultant high cost. On the other hand, distance phase relays have been universally accepted for transmission line protection. The combined phase and ground distance relay system proposed in the paper does not appear to reduce materially the number of elements required from those necessary for a separate phase and ground distance relay system. Moreover, the proposed common use of one set of starting units, having variable characteristics, by phase and ground relays places added restrictions on the phase relay operation and makes relay setting, testing and maintenance more difficult.

On the combined system, one set of three starting units is eliminated by using the same starting units for the phase and ground relays. The necessary equipment still includes three starting units, three phase-ohm units with a transfer relay, three ground ohm units with a transfer relay, one set of three blocking relays, and two timing units. It would appear that the omission of three starting elements would result in little, if any, saving in switchboard space and switchboard wiring. This would depend, of course, upon how the elements are assembled in the relay cases. There probably will be little, if any, difference in the installed cost of the combined relay system as compared to a separate phase and ground distance relay system.

It is noted that the starting units selected for this relay system are similar to, if not the

same as, those formerly used in GCX distance relays. These starting units are subject to change due to the collapse of the voltage triangle on phase to phase faults. As explained in a previous paper[1] the old type starting unit was replaced in the GCX relay because the variable characteristic made it susceptible to tripping on power swings. The size of the starting unit circle is a measure of the load carrying ability of the relay. Since it becomes necessary to increase the reach of this unit to assure clearing of line to line faults in the third zone, the load ability of the relay will be reduced correspondingly. Both of these facts make this starting unit undesirable for phase relaying.

The use of the same starting unit by the combined phase and ground relay system also may adversely affect the load carrying ability of the relay. As is stated in the paper and in a previous paper,[2] distance ground relaying must necessarily be of the reactance type due to the possibility of considerable arc resistance. On the GCX ground relays, zones 1 and 2 measure reactance, but it should be noted that zone 3 (starting unit) has an impedance characteristic. The reach of the starting unit should be sufficient to assure clearing ground faults with considerable arc resistance in the third zone. This means that on some applications the required reach of the starting unit may of necessity be so great that the load carrying ability of the relay may be materially reduced.

The combined phase and ground system does not seem to lend itself to testing or maintenance of individual elements while retaining partial circuit protection. The removal of any starting unit for maintenance or testing would render the associated phase and ground relay useless and would permit the other two ground relays to function incorrectly unless they also were removed from service. On the other hand, with separate phase and ground schemes the removal of a phase starting unit would render just that phase relay inoperative while the removal of any ground starting unit would render that ground relay inoperative and permit the other two ground relays to function incorrectly.

The setting of the relays on this combined system would be more difficult than setting of separate phase and ground relay. The setting of the starting unit might be rather critical, if not impossible, in certain applications due to the variable characteristics of this unit, the effect of arc resistance and the desired load requirements of the circuit.

It is not clear from Figure 13 of the paper how zone 3 trips for ground faults. This could be accomplished by connecting a $TU3_g$ contact from the common connection between A_g and O_g contacts to the trip wire.

W. A. Wolfe (Kansas Gas and Electric Company, Wichita, Kan.): This is a most interesting paper. It describes an improvement in phase and ground distance relaying achieved by combining in one element for each phase, the starting unit for phase and ground faults. Heretofore each phase and ground relay has had its own starting unit,

Figure 1. Impedance seen by ground relays during a phase A-to-ground fault

a total of six for a 3-phase line. The result is considerable simplification in the control circuits and also a reduction in current and potential transformer burdens.

I agree with the author that in most cases current compensation is to be preferred over potential compensation. One reason, not mentioned, is that for a relay system using potential compensation, the zero sequence reactance of the line must be accurately determined in order to set the relay correctly. Although the zero sequence impedance is used in setting the compensation of current compensated relays, the required accuracy is not as great. In current compensated relays, the positive sequence reactance which can be calculated to a higher degree of accuracy than zero sequence reactance, is the most important quantity.

This paper is valuable for another reason, in it the errors inherent in distance ground relaying are discussed and evaluated for the first time. As the author shows, for systems having solidly grounded neutral, which are probably the majority, the errors are such that they need cause no hesitation in applying distance protection for ground faults.

Warren C. New: Messrs. Frederickson, Streifus, von Roeschlaub, and Goldsborough in their discussions have pointed out that the starting units have variable characteristics which make them susceptible to false tripping due to power swings. It is true that a similar starting unit, in use for 15 years for phase distance relaying, was replaced in 1948[1] by a unit less susceptible to operation on power swings. However, as pointed out by Streifus and von Roeschlaub, the combination of conditions requiring less susceptibility to power swings is rare. Furthermore, the combined phase and ground distance relaying scheme described in this paper was designed primarily for subtransmission line applications where heavy line loadings or stability problems are not a serious factor.

Figure 2. Impedance seen by phase relays during a phase A-to-ground fault ($Z_{BC}' = \infty$)

Mr Goldsborough in his discussion questioned the ability of starting units of the unfaulted phases to perform correctly during a single-phase-to-ground fault. The ground distance relaying in use for the past ten years has used the same starting unit as this new system employs. While it is possible to imagine system conditions under a nearby phase-to-ground fault where the starting unit of an unfaulted phase may operate, no such false operations have been reported on the many relays that now are in use. Further, a system study and calculations made for a proposed application of this combined system reveals that at the station with the largest amount of fault current on the unfaulted phases, with load current added, and with a generous increase of starting unit reach, the starting unit had ample margin to preclude the possibility of false blocking for a ground fault in the tripping direction of the relays.

Apparently from the discussions received, there is some misunderstanding resulting from the way in which Figures 11 and 12 of the paper were drawn. These figures were discovered to be slightly incorrect and not entirely clear. For the reader's benefit, these figures have been clarified and are shown in the discussion as Figures 1 and 2. It should be noted that the scales for the two figures are not the same, Figure 1 using a reduced scale. As the discussers have pointed out, the third zone should adequately cover the protected line section and the next adjacent line section as is indicated in the redrawn figures.

The current compensation errors on heavily interconnected systems or on loop systems having a single source easily resolve into a single small error (determined by Z_0'/Z_1', see Appendix 1 of the paper) with homogeneous systems or possibly three small errors with nonhomogeneous systems. The five errors that are possible with the current compensation method as pointed out by Mr. Goldsborough are all small for typical transmission systems. This is shown by the error curves where it also is obvious that with solidly grounded systems or systems grounded through equal resistances the errors are small and in many cases negligible. Further, as Mr. Wolfe points out in his discussion, in applying the current compensated relay, it is not required that the zero sequence line impedance be known to nearly as great an accuracy as is required in applying potentially compensated relays.

It is believed that this combined system is a forward step in distance relaying since the economical aspects of the system make possible the application of phase and ground distance relaying to subtransmission line systems where it previously had not been economically justified.

Audible Noise of Power Transformers

T. D. GORDY
MEMBER AIEE

Synopsis: In the past few years, much emphasis has been put on audible noise of power transformers. Control of noise levels of such transformers without seriously affecting other important characteristics of the transformers is an important challenge to manufacturers. Sources of audible noise in power transformers, its attenuation and transmission, and the effect on designs are considered. Some characteristics of such noise are presented and methods of reducing noise levels are discussed. Power transformer noise problems confronting the manufacturer of such apparatus are discussed in relation to the over-all transformer design.

TRENDS in power system design require installations of large power transformers in thickly populated areas. These trends have been brought about by increasing capacities of existing stations and by transforming power closer to the ultimate customer than has been done in the past.[1] As a result, power transformer manufacturers have been asked to build low noise level designs for these installations. Simultaneous with these new requirements being placed on them, manufacturers have been developing new materials, processes, and material applications; and to advance the art, certain of these improvements are being incorporated in designs. The manufacturer then finds himself faced with the problem of designing for low noise levels and, at the same time, improving his product in quality, cost, and dependability. The way in which these two parts of the problem are related will be shown in this paper.

Sources of Noise

Transformers are becoming more complex because of their requirements, and no longer can the only source of transformer noise be considered magnetostriction. Even though magnetostriction is still recognized as one important driving source of audio noise, there are other sources, such as resonant parts or structures, vibrations at core gaps and joints, vibrations caused by interaction between core and coils, and vibrations of the coil conductors carrying current, which may result in noise generation or aid in noise transmission.

Magnetostriction

Magnetostriction may be defined as the change of dimensions of a magnetic material under magnetic stimulus. This is the only source of vibration in the core that is a property of the material, and true evaluation of this property can be obtained only with a d-c stimulus. D-c magnetostriction measurements may be made,[2] and results are similar to d-c flux-density-field-intensity data[2,3] in that a singly valued relation between magnetostriction and flux density is obtained on the initial magnetization of the sample. A loop is obtained if the flux density is increased, then decreased. Magnetostrictive characteristics are dependent upon the surface of the sample, the strain in the sample, and the heat treatment of the sample. Chemical composition of the steel also affects magnetostriction. Variation of d-c magnetostriction of transformer core steel with flux density in general follows a concave curve of three different types: (a), (b), and (c) of Figure 1, or, much less often, a convex curve (d) of Figure 1. Curves of Figure 1 are for the initial magnetization of the sample. If the flux density is varied through positive and negative values of flux, starting with an initially unmagnetized sample, the singly-valued curve goes into a loop as shown in Figure 2. Both the singly-valued curves and the loop show a nonlinear relation between magnetostriction and flux density. This nonlinearity requires harmonics in magnetostriction if flux density is varied sinusoidally.

In making a-c magnetostriction tests, factors other than the material in the sample may affect the shape of the a-c magnetostriction-flux density curve. Measurements of a-c magnetostriction have been made,[4] and a-c loops are similar to the d-c loop of Figure 2. If, however, the peak a-c flux density be increased to where it approaches saturation, the a-c loop becomes very much distorted, as shown in Figure 3. Again, vibration harmonics are generated; and since small sections of core laminations in joint regions are at very high flux densities during parts of the flux cycle, high-frequency components of vibration will exist around these sections.

Not only is the magnitude of magnetostriction important, but also the shape of the curve or loop is equally as important because of the harmonic phenomena involved. Even though one core material may have less magnetostriction magnitude than a second material, it may cause more effective noise emission than the second material unless its frequency distribution is confined to the fundamental and low harmonics.

Volume magnetostriction is another type of magnetostriction, but up to the present time, it is believed that it plays a negligible part in causing audio noise. In this type of magnetostriction, change in volume is considered instead of change in a linear dimension.

Gaps and Joints

Cores of power transformers usually are built by stacking many thin laminations into a structure. Necessarily, these laminations have junctions, joints, and gaps of one type or another through which flux must pass. Most such joints have overlapping regions in which the flux is divided between the parallel iron and air paths. Division of flux between the paths

Paper 50-8, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 7, 1949; made available for printing November 21, 1949.

varies throughout the cycle because of the variable iron permeability. Also, flux distribution in the corner sections of plate-type cores is nonuniform.[6] Across these gaps or joints in the core exists a force at each instant during the cycle that varies as the square of the instantaneous flux density. These forces tend to vibrate the leg and yoke sections of the core, thus becoming a source of noise.

If these regions had only fundamental flux in them, only a vibration and noise frequency of twice the core excitation frequency would be obtained. That is, if only 60-cycle sinusoidal flux were in the joint region, only 120-cycle vibrations would exist. However, with flux distortion and variable permeability in the joint regions, harmonics of the vibration and noise fundamental will be generated, and this in turn is emitted from the transformer, as will be shown later.

Resonating Parts

Most all materials which are built into a transformer have, either themselves or as a structure, mass and spring characteristics. This is true for the core, tank, radiator tubes, junction boxes, control cabinets, and so forth. Also, to some extent, there is a damping component associated with the mass and spring characteristics. Depending upon the geometrical shape, mass, elastic properties, and material of the part or structure being considered, resonant frequencies may be obtained that fall on or near one or several of the component vibration frequencies being supplied by the core. If damping is not sufficient, vibrations of these parts may be large enough to contribute to the transformer noise. Core vibrations have been described by Fahnoe;[6] if resonance of cooling tubes and other components exists, it may be necessary to modify the structure.

Although most of these resonating parts do not in themselves contain sources such as magnetostriction, they may, if not properly designed, be driven by other sources and amplify or easily transmit certain frequencies that would otherwise not be detected so easily. When a transformer has one of its major components, such as a tank wall, in resonance, the slope of the noise level versus excitation voltage curve is very small—much under the usual 2-to-3-decibel change in noise for a 10-per cent change in voltage.

Coils and Interaction Between Core and Coils

When current flows in a transformer winding, forces are exerted on the conductors and winding supports. An exaggerated case of such forces is the forces that occur when a transformer is short-circuited. However, at normal current densities used in power transformer designs, noise emitted by the coils due to their carrying load current is not enough to be appreciable. If the transformer must be designed for exceptionally low noise level, noise due to the coils may then become a source that cannot be neglected.

Similar to the coil noise, noise caused by vibrations due to forces between the coil and core and clamps is negligibly small in normal designs.

Fans and Pumps

Another source of noise which is not related to the transformer proper is the external cooling equipment. This equipment may be fans, pumps, or unit coolers. Usually, this equipment is mounted external to the transformer tank. Fans are mounted on radiator tubes or headers and, therefore, are a source of noise from one to several feet out from the tank. As will be shown later, the frequency spectra of fans and coolers are quite different from that of the transformer itself.

Figure 2. Representative d-c magnetostriction loop of transformer core steel

Damping Mechanisms

Vibrations caused by core displacement may be damped in three principal ways: damping in the core structure; damping in structural and metallic parts other than the core and coils; and damping in insulation. Complexity of the conventional power transformer structure makes it very difficult to segregate and evaluate these various types of damping.

In the core, steel itself may be damping. Part of this damping will be associated with the loss of energy associated with elastic vibration. In ferromagnetic materials these losses are generally larger than in nonmagnetic materials and may be interpreted in terms of other magnetic phenomena. Part of the damping in steel is due to eddy currents excited by the change of induction of the specimen as a whole, resulting from strain occurring during vibration. Still another type of damping is that caused by local changes of magnetization brought about by strain of vibration and accompanied by irreversible

Figure 4. Variation of noise level with excitation

Figure 5 (left). Variation of noise level with excitation frequency

Figure 6 (right). Block diagram of transformer noise circuit

displacement of the boundaries between domains. Damping by interstitial impurities within the iron crystal lattice may be caused by mechanical movement of the sample structure. Damping in core laminations is mostly a problem in metallurgy and physics; and until the various types are evaluated by these fields of science, the transformer design engineer cannot make much use of these characteristics.

Vibrations in structural parts such as clamps, tanks, braces, and so forth, are damped by energy loss related to elastic vibration. Some damping is present in layer and major insulations of the coils. However, all of the damping present in these parts of the transformer is not sufficient to reduce the noise emitted from a noisy core and coil structure to a value low enough to effect appreciable noise reduction. Also, the degree to which this type of damping is effective varies from design to design and is, therefore, not easily predicted and utilized in the design for noise reduction purposes.

Characteristics of Transformer Noise

Power transformer noise level is dependent not only upon the transformer itself, but also upon conditions imposed upon the transformer. Excitation voltage, magnitude and power factor of load current, and noise sources external to the transformer proper are some of these imposed factors affecting the total emitted noise from a transformer installation.

Variation of Sound Level with Excitation Voltage

Under no-load conditions, the variation of sound level with excitation voltage is dependent upon the type of core and core steel used in the core, as well as the operating flux density for which the transformer was designed. Given a design with a certain core material, the change in sound level per per cent change in excitation voltage will vary as the excitation voltage is changed. This is shown by Figure 4; curves (a) and (b) are for one type of core using two different steels; curves (c) and (d) are for two different cores of another type but using the same steel as curve (b). Curves (a) and (b) show a range of decibel versus per cent voltage slope from 0.55 to 0.12, depending upon the per cent voltage being considered. The corresponding range for curves (c) and (d) is 0.38 to 0.16. Around 100 per cent voltage, the change in noise level change is between 0.2 and 0.3 decibel per per cent change in voltage.

Curves of Figure 4 are for 60-cycle excitation; change in noise level for frequencies lower than 60 cycles is shown by Figure 5. The decrease in noise level with frequency is due to lowering the fundamental noise frequency and all of its harmonics. Necessarily, total noise level would be decreased because of the 40-decibels weighting characteristics specified by the standards for noise meters.[7]

Variation of Sound Level with Load

Present audio noise standards for transformers[8] specify that noise tests be made at 100 per cent excitation voltage with no-load on the transformer. In operation of the transformer, the problem still remains to determine what noise level the transformer will have under load if no-load noise level of the unit is known.

The degree to which load changes noise level is mostly dependent upon the way in which flux of the core is affected by load. Obviously, the type of core, type of windings, and winding arrangement must be considered. Also, in most cases, the noise level of the transformer is determined by the highest flux density in the core if as much as half of the total core steel operates at this high flux density. The problem then reduces to one of determining the variation of core flux density with load.

Basic transformer theory shows that

Table I. Representative Frequencies Present in Noise Emitted from 60-Cycle Transformers Rated from 750 to 37,500 Kva

induced voltage of the winding varies with the magnitude and power factor of load. Confining considerations to core-type concentric winding designs, it may be seen that:

1. Practically all reactance leakage flux returns through the core because of the high permeability of the core steel as compared with the parallel air path.

2. Addition of this reactance leakage flux to the main core flux will be vectorial; resultant flux in the core will be a function of load magnitude and power factor.

3. Variation of resultant flux in the core will depend upon which winding is being excited and which winding is connected to the load; that is, inside or outside winding as primary or secondary.

4. Resultant core flux will depend upon whether input or output voltage is maintained constant.

It is seen, therefore, that variation of noise level with load is closely related to the transformer design in a manner similar to regulation and must be considered as another characteristic dependent upon other specified characteristics.

Magnitude of noise level change may be as high as that corresponding to the core flux density being increased by the full reactance flux. For example, if the inside winding be excited, constant output voltage be maintained on the winding, a load of 10-per cent power factor lagging be supplied, and the reactance of the transformer be 10 per cent, change in noise level would be between two and three decibels. This would be an extreme case and for higher power factor loads with the inside winding as secondary, no change in noise level would be detected. Change in noise level because of load variation is, therefore, in the order of two to three decibels at the most and may vary all the way down to zero.

Noise Transmission and Reduction

Transmission of vibration and sound from the various sources to final emission to air is through a very complex 3-dimensional network. The simplified block diagram of Figure 6 shows the complexity of the circuit. Sources are shown in heavy blocks and direction of transmission is shown by arrow heads. Three sources are inside the tank and feed through the various components into the tank. On the tank another source, external cooling equipment, is added. From the tank, transmission may be directly to the air or through cooling tubes or heat exchangers and cabinets, then to air.

Even though transmission of vibration and noise in a transformer is very complicated, the diagram of Figure 6 shows the various locations either inside or out-

side of the tank at which noise suppression measures may be taken.

The core source and external cooling equipment source are the important ones to be considered. Core noise may be reduced by operating the core at low flux density. Present steels available for transformer cores have magnetic characteristics which make them desirable for operation at flux densities considerably above flux densities required for very low noise levels. Therefore, noise reduction by lowering flux density is very expensive besides giving rise to larger, heavier transformers. Another method of reducing core noise would be to eliminate gaps or joint sections. This may be done in small transformers,[9] but in power transformers it is necessary to use cores built up of many laminations instead of a continuously wound core. Still another method to reduce core noise would be to use core steel that has no magnetostriction at any part of the operating flux density cycle. Such a material, having this and other necessary characteristics, is not available to the transformer manufacturer at the present time.

Introduction of noise barriers inside the transformer tank is the only alternative for appreciably reducing noise transmission through the liquid insulation. This is, in effect, introducing high acoustic impedances in the transmission paths. Such barriers can be built, but they require additional space and weight, both of which should be held to a minimum in a well-balanced, economical design. Such additions, for acoustic reasons only, are necessarily expensive.

Fan or cooler noise may be reduced by either using special design, low-noise-level fans which have reduced cooling capacities, or by reducing the operating speeds of standard transformer cooling fans. Reducing fan speed 50 per cent may give noise reductions as high as 30 decibels. To cool transformers with such fans, it is necessary to use many more of them than would be used if they were operated at their standard speeds. Again, this noise reduction is expensive.

Frequencies of Noise

Necessary for noise reduction studies of power transformers are the frequencies present in emitted transformer noise. Frequency composition of emitted noise varies from position to position around a transformer, but by analyzing several positions around the transformer, the important frequencies with which to be concerned may be determined.

The simplest and most accurate method of obtaining and recording component frequencies is to put the output of the sound level meter into an analyzer and recorder. The recorded trace then is a plot of sound level in decibels versus frequency, such as that shown in Figure 7. Traces of this figure are for transformers without cooling fans, and rated 1,000 kva. Peaks of the various component frequencies then may be read. Summation of the component frequencies then may be checked against the sound level meter reading. All data in this paper were taken with the 40-decibel weighting scale.

In Table I are tabulated frequencies for several transformers to show how frequency composition varies from one transformer to another. From this tabulation, it may be seen that, for 60-cycle supply voltage, a range in frequency from 120 to 1,200 cycles must be considered for noise reduction purposes. Transformer noise is characterized by peaked finite frequencies; whereas most fan noises have a large component of broad-band noise, as shown in Figure 8. Although peaks may be present in fan noise, a large part of the noise of most transformer cooling fans is contributed by broad-band noise.

Design Characteristics and Requirements

The primary purpose of a power transformer is to transform energy from one circuit at one potential level to another circuit at another potential level. In some cases, more than two circuits are tied in by the transformer. Depending upon the application of the unit, a few or many specific requirements must be met by the design. Impedances may be specified, efficiencies may be specified, a certain regulation may be required, floor space and total weight may be a limiting factor, shipping dimensions and weight are limitations, temperature limits must be observed, and core and copper losses must meet specified values. These and many more similar characteristics determine the degree of flexibility available to the designer. Because of these varied and interrelated functional characteristics, the designer must consider the design as a whole. One particular requirement cannot be designed for, without considering its effect on other requirements.

The increasing importance of transformer noise imposes another constraint on the transformer design.

Simultaneous with the imposition of more requirements being placed upon the design, the manufacturer has been developing new materials, new manufacturing processes, and improving design practices to enable him to build better, more efficient, and more reliable transformers. While making these changes, the manufacturer has constantly kept in mind the requirements of, and his responsibility to, the customer. Where new materials have been introduced, their ranges of operating temperature, stress, voltage, and flux density have been determined such that the new material would be properly applied in designs. Having these developments together with his past experience, the manufacturer is definitely interested in improving his product by using new materials, processes, and techniques.

Cost of Noise Reduction

At the present state of the art, reduction of power transformer noise levels below present standard values requires either a reduction in operating flux densities or introduction of acoustic impedances in one or more of the transmission paths. Such impedances may be internal or external to the transformer tank. Either of these reduction methods is expensive and places handicaps on the designer. Lowering noise levels of cooling equipment requires either slow-speed standard fans or redesigned low-noise-level fans which are not as efficient on cooling as present standard fans. Either of these methods is expensive. Therefore, noise level reductions of the transformer itself are expensive and may necessitate cost increases of power transformers.

The other alternative for obtaining low-noise-level transformer installations is to build walls, barriers, or enclosures around the transformer. This method sometimes requires cooling equipment for the installation, is difficult to arrange for incoming and outgoing voltage lines, and, to a certain extent, imposes fire protection and repair handicaps. In metropolitan or residential areas, such measures may have to be used, but at stations remote from such areas or in noisy areas, present standard transformer noise levels would be satisfactory. It appears that installations requiring very low noise levels should be considered as special installations.

Whether extra expense required to obtain a low-noise-level transformer installation be put into the transformers themselves or in walls, barriers, and structures is a matter of which method is less costly. Operators and manufacturers will have to work together to obtain the most desirable solution which probably will vary with the installation.

Conclusions

Characteristics of power transformer audio noise vary from one design to another, but the more important characteristics, such as variations with excitation voltage, load, frequencies present, and size of transformer, are fairly well established. Increased importance of transformer noise requires the manufacturer to be very much aware of these characteristics because of the interrelation between audio noise and other characteristics.

For special installations, low-noise-level transformers may be designed and built, but they are costly. The other alternative of building enclosures around transformers also is expensive and disadvantageous in other respects. For such installations, the best compromise can best be worked out by the operator balancing costs, advantages, and disadvantages of the two possible methods. Either method will increase cost over that of a standard transformer, but such cost may have to be borne for particular locations.

Discussion

A. P. Fugill (The Detroit Edison Company, Detroit, Mich.): Mr. Gordy's paper represents one viewpoint on the subject of quiet transformers which, I believe, is rather typical of the manufacturing companies. Other papers at the session present the typical user's viewpoint. As I interpret these views, most manufacturers believe that no large segment of the transformer-buying industry needs transformers much quieter than the present ones, and, if quieter transformers are needed, they will cost more. Some utility users know the transformers they have been receiving under the present noise limits are not quiet enough for many installations, and believe that quieter transformers could be obtained with little or no increase in cost, if sufficient attention were given to the noise factor in transformer design and manufacture. The natural conclusion is that the present National Electrical Manufacturers Association standard limits for noise in transformers should be changed, but the manufacturers would like to raise them and the users would like to lower them. If the limits are raised too high, the installations where quietness is essential will carry a disproportionate amount of the cost, and, if they are lowered too far, installations where quietness is of no importance will be penalized.

A number of points have been brought out which, though important, are subordinate to the main point at issue, which is the determination of the proper set of noise limits to serve the best interests of the whole industry. For instance, complaints have been made against the present sound level meter. We must realize that we have an impossible task if we try to make a meter which will match the sound perception characteristics of even a million people, each one of whom differs not only from the others but from himself at different times and under different conditions. Certainly we should try to improve our measuring equipment, but the present sound level meter is entirely adequate to differentiate between a transformer which will cause trouble and one which will not, if only the requirements are known. The greatest variable is not in the meter, but in the people who live next door to our substations.

The techniques of measurement seem to be causing some concern. The location of the microphone, the effect of the ambient, and the weighting network to be used are important. Perhaps the present methods and standards can be improved upon in the light of modern knowledge. But the use of a different weighting uetwork in the meter will not make the transformer being measured any quieter, nor will it point the way to an economical design for a quiet transformer.

More important than either of these factors is the basic research into the causes of noise in transformers and the development of inherently quiet designs. In time, we may discover how to design a quieter transformer without the proportionate increase in cost. But even this problem does not rate top priority. Though some may disagree, I believe the present knowledge is sufficient to produce transformers which will meet most of the present needs of industry. The question is not so much whether we can obtain quieter transformers but rather whether that is the economical way to obtain the quietness we need.

Since about 1939 all manufacturers have been designing to meet the limits imposed by NEMA standards. Perhaps a look at their performance in terms of the transformers which have been received by The Detroit Edison Company may be helpful in determining the proper noise limits. In considering these data, note that The Detroit Edison Company has been using noise specifications since 1937 and had been stressing quietness in transformers for several years before that.

The curves shown in Figure 1 of the discussion were obtained from the measurement of noise on 252 transformers from 500 to 10,000 kva, mostly 24,000/4,800 volt, which we received during the period from 1916 through 1949. They cover virtually all the transformers in this class that we have purchased. The results are plotted in terms of deviation from the present NEMA standard limits in order to fit all sizes into the same curve. The curve used is essentially a cumulative distribution curve by which the percentage of transformers that equal or exceed a given noise level can be read directly. We have classified all transformers, regardless of size or manufacturer, into three age groups. The dashed curve covers 96 transformers received in the years 1916 through 1930, during which time there were no noise specifications in use. Practically no transformers were purchased in the years 1931–1936, so the solid-line curve is for the 61 transformers received from 1937 through 1942, during the period when noise specifications were in use and before the influence of the war was felt and different core materials were used. Very few transformers were purchased in the years from 1943 through 1946. The dotted curve covers the 95 transformers received from 1947 through 1949, the post-war years when newer core materials were available, and situations resulting from production during the war may have had an influence. From these curves, you will note that in the 1916–1930 period, 70 per cent of the transformers received did not meet the present specification limits. That is no indictment of the manufacturers, of course, because the present specification limits did not exist in that period. For the 1937–1942 period, 13 per cent of the transformers received were over specification limits. This is a very appreciable improvement, when compared with the upper curve, but possibly not such remarkable performance when you remember that the specification limit was set up as a maximum figure with no intended tolerance. In the 1947–1949 period, however, 33 per cent of the transformers received were over specification limits, a very definite backward step. This is the situation which raises the present concern over noise limits.

From this evidence, and similar findings by other utility companies, it is clear that a rather significant proportion of modern transformers is not meeting even the present NEMA standard limits. Furthermore, it has been our experience, substantiated by the experience of others, that even transformers which meet the present limits are much too noisy for some installa-

Figure 1. Percentage of transformers measured (500–10,000 kva) that equaled or exceeded indicated sound levels

tions, and remedial measures must be applied at considerable cost.

Since there is such a divergence of opinion, however, it is important, before any change is made in these limits, that additional information be obtained from all segments of the industry—manufacturers, utility users, and industrial users. Three questions need to be answered, and only after the answers are obtained will we be sure that we have solved the problem in such a way that the lowest cost to the industry will result. First, what sound level limits are really needed, if due regard is given to the average situation as well as the extreme ones? This is a job for the users, not the manufacturers, and the users who have no noise problems are just as important as those who have. Second, how does the true cost of the transformer vary with the sound level, if the designer gives the noise factor equal status with such other design factors as reliability, weight, and losses? Third, what is the cost of the remedial measures external to the transformer, which can be used to make the transformer acceptable? These facts are not easy to obtain and they vary over a wide range. But a thorough-going investigation on a wide front, with an earnest effort on the part of all concerned, will go a long way towards establishing the optimum values of sound level limits for transformers.

J. E. Goldman (Westinghouse Research Laboratories, East Pittsburgh, Pa.): It is apparent from Mr. Gordy's paper that noise in transformers is a very complicated phenomenon and to understand it quantitatively requires the solution of complex mechanical, electrical, and magnetic problems. One of the principal, although by no means exclusive, magnetic problems that arises is that of magnetostriction. A full discussion of the fundamental aspects of magnetostriction and its measurement by this writer is on the agenda of the magnetic symposium tomorrow. There are, however, a few points pertinent to Mr. Gordy's paper that it may be well to bring up here.

It is correctly pointed out that the only true measure of the macroscopic magnetostriction is by means of d-c measuring techniques. This is because the vibration measured under a-c excitation may include amplified components due to mechanical resonance of the whole or a part of a sample but which may be different if the sample geometry is changed. In this connection it is to be noted that in a transformer core the core resonances and local resonances merely amplify the effects normally produced by excitation forces which are necessarily magnetic in origin; resonance in itself we do not believe to be a source of vibration as implied by Mr. Gordy. An individual sample when measured under a-c excitation is essentially a small transformer core with the same mechanical and magnetic complexities. Moreover, most existing methods of measurement under a-c excitation that we know of introduce measuring errors that may tend to exaggerate a given harmonic of the magnetostriction spectrum. For example, most piezoelectric crystals have resonances between 600 and 1,000 cycles. Use of a crystal pickup in an a-c magnetostriction measurement may, therefore, tend to exaggerate the higher harmonics and change both the amplitude and shape of the curve completely.

The term macroscopic magnetostriction was employed in order to distinguish it from the more fundamental magnetostrictive lattice distortion of the unit cell which we shall call the microscopic or spontaneous magnetostriction. The latter is a basic property of the magnetic material that depends primarily on the composition of the alloy and can be measured only by an involved set of magnetostriction measurements on single crystals in various crystal directions. The former is measured by noting the change in dimensions of the sample in a given direction; its magnitude is conditioned largely by the crystal and domain orientation. Nonrandomness of the distribution of the domain direction such as may be achieved by cold rolling can bring the measured macroscopic magnetostriction down to a very low value in a material that normally has a large basic microscopic magnetostriction. Such is, in fact, largely the situation with cold rolled oriented sheet steels.

This suggests an important shortcoming in the methods used by many manufacturers and employed by Mr. Gordy in interpreting the influence of magnetostriction on transformer noise. The measurements of the magnetostriction are macroscopic and often show that the material changes its dimensions to only a minor extent. Yet, had the measurements been made in other than the direction of normal magnetization, the magnitude of the magnetostriction may be significantly larger and the shape of the $\Delta l/l$ versus B curve perceptibly different. In a transformer core, there are regions where the flux is not in the direction of the sheet. This is particularly true in the neighborhood of the joint but is to some extent prevalent throughout the iron circuit. In these regions, therefore, the magnetostriction and resulting vibration can be quite large in a direction transverse to the direction of flux.

The usual measurement of magnetostriction on sheet steel samples gives no indication of the magnitude of this type of magnetostriction. In point of fact, the latter is quite large for oriented sheet steels in which we are accustomed to viewing the magnetostriction as being small. This also is to some extent true of the silicon steels with high silicon content.

The question of coil noise is one that often comes up for discussion and has been raised by Mr. Gordy. It has been our experience that coils do not contribute measurably to the total noise of the transformer. Many tests over an extended period of time in which cores were first tested with only a skeleton winding and later as assembled with the coils and finally under operating conditions in the field seem to substantiate this viewpoint.

In general, the complex problem of transformer noise has been treated quite adequately by Mr. Gordy and he should be commended for introducing many aspects of the subject that are of more than casual importance but that have been somehow neglected in previous discussions of this subject.

C. C. Horstman (Westinghouse Electric Corporation, Sharon, Pa.): Mr. Gordy has presented a very excellent paper covering the factors involved in the design and use of power transformers with regard to sound level. It is certainly true that in order to reduce the cost and improve the quality of power transformers the manufacturer has to design to use higher operating inductions. These higher operating inductions are made possible with the better core materials available today, but unfortunately, full usage of these higher inductions is incompatible with sound level reduction unless further development takes place.

The author, in his paper, makes a very good listing of the sources of noise, and we certainly agree that mechanical vibration sources are as important as magnetostriction. It is to be noted that resonance is not strictly a driving force, but is an amplifying

agent for noise. We have found that excessive noise due to resonance can be largely eliminated by designing specifically to avoid the fundamental frequency and its multiples in our various structures. It also may be pointed out that the effect of resonance reducing the slope of the curve of sound level with voltage as described by Mr. Gordy may or may not be true because it depends on the particular harmonic which is driving the resonant part, the amplitude of which usually varies with the induction.

The author's comments on core joint influence are very good. We have found that butt joints in wound cores perform very well, even in large sizes, provided the joint surfaces are bound together sufficiently well to eliminate simple joint vibration. We certainly concur that flux distribution in the joint is a very important factor influencing sound level.

In the author's discussion of damping mechanisms he refers to damping in the core steel itself. It is not clear whether or not this is a process by which the magnetostriction is reduced. We know, in general, that the better the magnetic properties of the core material the lower its inherent basic magnetostriction. This to me would preclude the damping or lowering of magnetostriction vibration of the core steel by effects, such as strain or lattice impurity, causing harm to the magnetic characteristics. It is true that information on these causes and effects is meager and requires further study.

It is quite another situation though in regard to vibration of the structural parts, such as tanks, braces, clamps, and so forth. Here improvement has been accomplished, by proper design, to effectively reduce sound level by effective means of core clamping, bracing, and mounting.

The author has summed up the requirements for sound level reduction and its probable influence on cost very well. It may be pointed out that the use of internal barriers is very complex and expensive. The problem of adequate cooling without making the transformer unnecessarily large is encountered at once because it must be remembered that while the barrier will insulate against sound transmission, it is as equally effective in preventing heat transmission to the oil or cooling medium. It also is to be noted that cooling oil pipes or ducts, where they come out through the barrier, present a design problem to avoid the transmission of sound energy to the outside along these avenues. It also should be pointed out that the very nature of such devices as internal barriers makes successful operation in hot oil over an extended service life very doubtful.

It is very evident that at this stage of development the operators and manufacturers will have to work closely together to obtain the best solution, which, as the author points out, will probably vary with the installation. It cannot be overemphasized that a decrease in operating induction is an expensive solution to lower sound levels.

C. S. Murray (Consolidated Edison Company of New York, Inc., New York, N. Y.): Mr. Gordy is to be commended on outlining the sources of transformer noise in a language that can be understood by those using the transformer, the power engineers. He has done an excellent job in outlining and discussing the fundamental aspects of transformer noise insofar as it is related to transformer design.

The author outlines five major sources of the noise from the transformer itself. Later on in the paper it is indicated that two of these sources, that due to coil conductors carrying current and that due to forces between coil and core, are negligible in transformers of normal design but may have to be considered in those designs calling for exceptionally low noise levels. Most noises from resonating parts are negligible in transformers where reasonable care has been taken in the design and where the knowledge gained from past experience has been applied. This results in magnetostriction and the vibrations at the core gaps and joints being of outstanding importance. These latter two sources of noise also were found to be the principle ones in the investigation carried out by the British Electrical and Allied Industries Research Association in the late 1930's.

Mr. Gordy points out the importance of the shape of the magnetostriction loop because of the harmonic phenomena involved. This is of the utmost importance to the user since the higher frequency noises are radiated more efficiently from the core and the human ear is much more sensitive to them. Therefore, if a steel could be found having a shape for the loop which would result in only the lower frequencies of noise being set up, the loudness of the noise radiated would be reduced and the loudness of the noise would decrease more rapidly with increase of distance from the transformer.

The author discusses noise due to the core gaps and joints but does not point out how the transformer designer attempts to decrease it. The question is raised as to whether a greater problem exists here other than properly designed core clamping.

There is still another source of noise in those transformers equipped with tap changing under load equipment using a series transformer. With the tap changer in the full-buck or full-boost position, the average sound level of the transformer may be as much as 4 to 5 decibels above that value when the tap changer is in the neutral position. The design of the series transformer must not be overlooked.

Transformers have been received from manufacturers wherein mechanical noises, some high pitched and others low pitched, have been emitted. In some cases, either loose or unequal tightening of the radiator tube bracing bands have allowed the tubes to vibrate against the bands. In other cases, the fan control conduit was run too close to the tubes which vibrated against it. In the case of these noises, the transformer designer may have taken care of them on the drawing board, but it never reached the finished product.

Location of these local noises and their elimination could only be made in the field after the transformer was energized. If this noise had not been attended to immediately it could have been the basis for a noise complaint and, as I have stated elsewhere, once a complaint arises, a series of noise complaints usually follow because the complainant is made noise conscious.

The paper points out the problem of transformer cooling fan noise. Just how much noise may be emitted by fans can be judged from the results of sound level measurements made on a 60-megavolt-ampere transformer equipped with 18 fans mounted on the radiators around the periphery of the transformer. These fans, each consisting of three blades, $19^1/_2$ inches in diameter, and operating at 1,750 rpm, are sufficient for increasing the rating by 25 per cent. Tests, made in accordance with the method outlined by the NEMA Standards for Transformers[1] with the fans in operation but with the transformer deenergized, showed an average sound level of 74 decibels. Tests on a single fan, three feet from its hub, resulted in an average sound level of 73 decibels.

In general, as Mr. Gordy points out, most of the noise from a fan is a broad-band noise. Some fans, in addition to emitting the broad-band noise, emit a pitched noise having a frequency or harmonics of this frequency equivalent to the product of the number of blades and the speed of the fan in revolutions per second. This pitched noise might be objectionable in some installations unless it becomes masked by the transformer noise. Fan designs resulting in an appreciable component of pitched noise should be avoided for quiet transformer installations.

In addition to the noise characteristics of the individual fan, the mounting of the fans must be considered not only in regard to efficient cooling but also in regard to the noise. Tests have been made on a transformer which indicate that the noise attributed to the fans may be greater with the transformer energized than with it deenergized. Tests on another transformer show an increase in sound level for some of the component frequencies present in the transformer noise and introduction of higher harmonic frequencies due to the operation of the fans. Yet, the results of tests made on an individual fan in the laboratory do not account for the change in the components of the noise emitted by the installation.

In those installations having transformers with triple ratings the fan problem may be minimized by obtaining the first step in increased rating by means of forced-oil cooling instead of forced air as is the present practice. The load curve for the particular installation may permit the use of the second step, that is forced oil-forced air, only during the day time when higher ambient noise levels usually exist. However, if the transformer is installed in a tie feeder where the second step may be necessary at any time, the fan noise remains a problem.

The author describes a method of obtaining a measure of the component frequencies around the transformer. If he wishes to imply that it is more accurate to record the output of the analyzer, I disagree with him. The mere recording of a value will not change the accuracy of the value measured. There are advantages in recording when making tests in the vicinity of the transformer, one of them being that if the audio band is scanned a complete plot of the transformer components is available right there on the job. It is simpler to look at a plot of values rather than a large number of figures. However, at distances remote from the transformer there may be more disadvantages in recording particularly if the audio band is scanned. Transformer noise

remote from a transformer varies in magnitude and, if the analyzer is driven through a transformer frequency at the time when this component is a minimum, the recorded value will not be a proper one. It would be necessary to record each particular important frequency over a period to obtain the proper values. Then, again, the operator, while recording is in progress, must mark the chart when extraneous noises occur which contain the frequency being recorded. When a peculiar value is noted on the chart the question often arises as to whether an extraneous noise existed and the operator failed to mark the chart.

In Table I is listed the component frequencies of some transformer noises. In my experience with distribution and power transformers the component frequencies from 120 to 480 cycles have generally been of the major importance. However, the results for the transformer identified as "B" show the outstanding component to be 1,200 cycles. The use of such a transformer should be avoided even in a location where only a fair degree of quietness is desirable. The question is raised as to whether this noise has not resulted from improper core clamping.

The reduction of transformer noise by means external to the transformer is costly as the power engineer well knows and as the author also recognizes in his paper. In the past, most installations have been made quiet by means external to the transformer. In the last few years, however, many users have begun to feel that an economically quiet transformer can only result by a reduction in the noise at its source. This may mean the use of steel having proper magnetostrictive properties together with the application of the knowledge available to the transformer designer.

Reference

1. See reference 8 of the paper.

T. D. Gordy: Mr. Fugill considers the major problem as that of determining a set of noise limits that will serve the best interests of the whole industry. He points out phases of the problem which must be solved by the manufacturers. We, as a manufacturer, are working on the basic causes of transformer noise and development of quiet designs. However, satisfactory improvements in noise level must be obtained without seriously handicapping other important functional characteristics of the transformer. Introduction of cold-rolled steel into power transformers has resulted in lighter, more efficient and smaller transformers. Possibly, manufacturers have used cold-rolled steel prematurely so far as noise level is concerned, but other improvements, such as reductions in core loss, exciting current, weight, and dimensions, have been passed on to the users.

The curves presented by Mr. Fugill indicate that transformer levels were higher during 1947–1949 than during 1937–1942. In the period 1947–1949, however, manufacturers were under several handicaps. Increased output, serious shortages of some materials, new and partially-trained technical and factory personnel, and loss of continuity of development during the war were handicaps that would allow shipment of transformers that might exceed noise specification limits. Also, margins between test values and specification limit values were decreased. Conditions existing in 1947–1949 are not so prevalent now, and an improvement in meeting specification limits on the part of the manufacturer should be realized.

Mr. Murray's comments on change in noise level with tap position on tap-changing transformers using series transformers are certainly justified. Depending upon the relative kilovolt-ampere ratings of the main and series transformers, effect of excitation on the series transformer may be anywhere from negligible to 4 or 5 decibels. However, whether the series transformer is or is not excited at no load depends upon the particular design under consideration, and present standards specify only no-load noise level. Revision of the standards should include the effect of the series transformer.

Properly designed core clamping is only one factor in minimizing core gap and joint noise. Type of joint, location of the joint region in the magnetic circuit, and flux distributions in joint regions are other factors which affect gap and joint noise. Developments along these lines have shown improvements not only in noise, but also in core loss and exciting current.

Radiator tube bracing bands, control conduit, and other similar parts of the transformer cause undesirable noise emission as Mr. Murray has observed. These items may be checked in the engineering and drafting stage and again when the transformer receives factory tests, but some parts still vibrate after installation. Careful inspection of the installation must be made in addition to inspections made at the factory. Even though the vibrations may not be serious so far as transformer life and functional operation are concerned, they may be annoying to an observer. This, together with the discussion of fan noise given by Mr. Murray, shows the importance of the psychological part of noise evaluation.

Mr. Murray is correct in stating that recording values of component frequencies does not increase the accuracy of the value being measured. Recordings have the advantages discussed by Mr. Murray, and they also give a permanent record that may be reproduced.

Transformer "B" of Table I was selected as a representative unit of a particular type and kilovolt-amperes. A 1,200-cycle predominant component was not unique for the particular unit of Table I. Investigation of that type and kilovolt-amperes of transformer has not shown that the high-frequency component was caused by improper core clamping.

As Mr. Horstman states, harmonic composition of the driving force varies with induction. However, if sufficient power at any induction is available to maintain resonance, and if resonance is an important contributing force, the slope of the noise-level-voltage curve will be decreased. As a specific example, a transformer was found to have serious resonance of some parts at 120 cycles. Total average noise levels measured at various percent voltages were:

Per Cent Voltage	Noise Level, Decibels
90	71.7
95	72.0
100	72.1
105	72.6
110	73.1

Variation of noise level with per cent voltage is much less than the normal value of 0.3 decibel per per cent change in voltage. As has been pointed out by Mr. Horstman and Mr. Murray,[1] designing specifically to avoid fundamental frequency and its multiples will considerably reduce resonance.

In the paper, various types of damping that could exist in the core steel were mentioned but not discussed in detail. How these types of damping affect magnetostriction was not stated. As the paper states, damping in core laminations is a metallurgical physics problem which requires further study. Therefore, Mr. Horstman's question of whether or not damping reduces magnetostriction must await additional study.

Mr. Goldman's discussion of magnetostriction is most timely, because magnetostriction is an important source of noise. Short treatment of magnetostriction in the paper was intentional because, as Mr. Goldman's discussion shows, complete treatment of magnetostriction is in itself enough material for another paper. Studies of basic metallurgical physics problems should include details brought out by Mr. Goldman, but such findings must be put into a form that may be used by the engineer before they are fully utilized in the transformer designs. Magnetostriction as used in the paper determines vibrations of the leg and yoke members as whole vibrating bodies. Noise resulting from spontaneous magnetostriction may or may not be as important as that resulting from macroscopic magnetostriction; experimental evaluation of the relative magnitudes of noise from the two types of magnetostriction is needed.

Discussions by Mr. Horstman and Mr. Goldman agree with the paper on the complexity of the transformer noise problem. Users, as represented by Mr. Fugill and Mr. Murray, require quieter transformers without excessive cost. Obviously, a compromise must be reached, and it is only through close co-operation between manufacturers and users that a satisfactory solution will be otained. This was recommended in the paper and in three of the discussions. Although the manufacturer is faced with a difficult problem, developments under way show promise and are encouraging, and it is reasonable to expect a satisfactory solution will be obtained.

Basic Patterns for Arrangement of Electric Power Systems for Steel Mills

HARVEY J. FINISON
MEMBER AIEE

THE steel mill power systems to be discussed in this paper may be as small as about 15,000 kw installed capacity and may approach or even exceed a capacity of 200,000 kw. If the steel mill has blast furnaces and coke ovens with waste fuel available, part of this capacity will be from turbine generators. Where possible there will be a tie to the electrical utility; and in many mills all of the electric power is provided by the electrical utility.

The utilization voltages for the steel mill usually will include 440 volts, 2,300 volts, and 6,600 or 13,200 volts for the large motors or furnaces. Generation will usually be at 6,900 or 13,800 volts, although some older 2,300-volt machines are still in service. Formerly there was only limited use of voltages above 6,900 but there is an increasing need for higher transmission voltages. These include 22, 33, and 69 kv.

Steel mill power systems are somewhat different than those for other industries:

1. The systems are usually larger in capacity than for most other industries.
2. There are large unit loads—large motors and electric furnaces.
3. There are large fluctuations in load.
4. The location of generating capacity is dictated by availability of waste gas fuel rather than by electric load requirements.
5. There is severe exposure to dust and dirt.

Paper 50-9, recommended by the AIEE Industrial Power Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted April 15, 1949; made available for printing November 22, 1949.

HARVEY J. FINISON was Application Engineer, Industrial Engineering Divisions, General Electric Company, Schenectady, N. Y., at the time this paper was prepared. He now is Assistant Chairman, Electrical Engineering Research, Armour Research Foundation, Chicago, Ill.

Steel Mill Installation Problems

To maintain adequate insulation levels for outdoor structures and over head lines, it is usual to provide insulation levels above actual system voltage and to clean insulators at least once a year, although some require cleaning every three months. Cleaning is expensive and must be accomplished at a time when the parts being cleaned can be taken out of service. Additional circuits or busses may be required in order that those being cleaned may be conveniently taken out of service; or economic compromises may dictate the acceptance of reduced reliability during the cleaning operation.

Substantial freedom from frequent maintenance cleaning can be obtained for the steel mill power system by these methods:

1. Use of metal-enclosed switchgear installed in air-conditioned rooms where necessary.
2. Use of insulated power cable rather than open overhead lines.
3. Use of cable or enclosed bus connection to all transformers.

These methods also improve safety since the entire power system may be enclosed in grounded metal.

Cable

Underground cable gives freedom from adverse weather or other operating conditions, good protection from accidental disturbance, and permits compact construction in and around buildings. It is desirable for steel mill systems although for many areas underground construction is a handicap. For these areas, aerial cable has many advantages:

1. Virtual elimination of lightning problems.
2. Ability to construct a line close to or even hung from building structures.
3. Elimination of insulator cleaning.
4. Improved safety.

For aerial cable overinsulation is not required, since the steel mill service has little more serious effects than service in any other industry. Additional savings in lightning arresters, reduced space and congestion at the power house and other terminations, and the reduced main-

tenance make aerial cable compare favorably in cost with open overhead lines.

Switchgear

The economics of switchgear application will be a major factor in selection of voltage levels and in the arrangement of the steel mill electric power system. A summary of the characteristics of the types of circuit breakers that will be considered is given in Table I. Only indoor types with steel enclosures are included in this list since these will permit obtaining a safe reliable system with freedom from the frequent insulator cleaning required for outdoor types in steel mill areas. The 500-megavolt-ampere interrupting rating circuit breaker listed is of typical metal-clad construction and of the oilless type. See Figure 1. The 1,000- and 1,500-megavolt-ampere circuit breakers listed are station-type switchgear in steel cubicles and of air-blast type of operation. Figure 1 (left) shows a typical installation.

System without Current Limiting Reactors

Consider that a steel mill electric power system is solidly tied together without use of reactors to limit short-circuit currents, and assume that the system is in a small area so that impedance of interconnecting lines may be neglected. What is the maximum system capacity that may be connected into such a solidly tied system without exceeding the short-circuit ratings of the different circuit breakers?

Figure 2 shows the assumed constants used for calculating the short-circuit currents to obtain the answer to this question. Included are generators and motor loads of typical capacity and reactance. Frequently part or even all of the capacity here represented as a generator may be a tie to an electrical utility; where the tie is through a transformer, the reactance value shown would still be representative. Where the utility tie is direct to a main power station at the steel mill voltage level this may not be a good assumption, since there may be little impedance to limit the fault current delivered by the electrical utility system.

Figure 3 shows the results of calculations to determine short-circuit currents for systems of various capacities by methods described in references 1, 2, and 3. Shown in Figure 3(A) is the momentary current rating required of circuit breakers to be used on the system. Figure 3(B) shows the interrupting duty in megavolt-amperes. Shown at the right of each chart is the corresponding rating of circuit breakers selected from Table I. The size of the circuit breaker is designated in terms of its interrupting rating in megavolt-amperes. These charts will give the maximum system capacity that can be allowed for each of the circuit breaker ratings shown.

For example, what is the largest system capacity at 6,900 volts that can be allowed for 500-megavolt-ampere switchgear? Figure 3(A) shows that a system capacity of 38,000 kva will give a momentary short circuit current of 80,000 amperes, the maximum rating of the 500-megavolt-ampere switchgear. Figure 3(B) shows that 500-megavolt-amperes interrupting rating would permit application on a system up to 45,000 kva.

Figure 2. Constants of steel mill power system assumed for short-circuit calculations

Figure 3. Results of short-circuit calculations on typical system with no impedance in tie circuits

Figure 4 (left). Use of reactors to limit short-circuit current

Figure 5 (above). Typical synchronizing bus arrangement

For this example the momentary short-circuit current is the limiting factor and the maximum system capacity permissible for the 500-megavolt-amperes switchgear would be 38,000 kva.

Similar maximum system capacities for the other circuit breaker ratings are summarized in Table II. For 13,800 volts and above the momentary duties do not approach the momentary rating of the switchgear and interrupting duty is the limiting application consideration. The more limited ability to expand power systems at 6,900 volts as compared with 13,800 volts and higher is emphasized by Table II.

These statements do not mean that for systems smaller than the limits listed in Table II it would be possible to arrange the system without consideration of the arrangements that would be required by expansion beyond those limits. It should be the objective to arrange the system in such a manner that it can be conveniently expanded as may be required by any future needs.

Short-Circuit Level at Loads

In a steel mill there will be appreciable utilization equipment and considerable distribution at either the 6,600- or 13,200-volt level. For switching load and distribution circuits 500-megavolt-amperes metal-clad switchgear is now, and is likely to continue to be, the most popular switchgear.

In general, it will be found uneconomical to use higher than 500,000 kva interrupting capacity circuit breakers for this service and there appears to be no requirements indicating that a higher capacity will be required. Therefore, we must consider an arrangement of a power supply system to limit short-circuit currents to the 500-megavolt-amperes level at 6,900- or 13,800-volt busses.

Table II shows that the maximum system capacity which can be interconnected without exceeding the rating of 500-megavolt-ampere switchgear is about 30,000 kw at 6,900 volts and 36,000 at 13,800 volts. These will be recognized as comparatively small steel mill power systems. For larger systems, arrangements using reactors will be required to limit the short-circuit current.

Table II. Maximum System Capacity for Various Size Circuit Breakers Without Use of Reactance for Limiting Fault Currents

Circuit Breaker Rating, Megavolt-Amperes	500	1,000	1,500

13.8 or above	45,000	91,000	137,000
Capacity in Kilowatts*			
6.9	30,000	34,000	58,000
13.8 or above	36,000	73,000	110,000

* Assuming generators rated 0.8 power factor. Figures are rounded.

Use of Reactors to Limit Fault Currents

Figures 4(A) and 4(B) show arrangements using feeder reactors. In Figure 4(A) the reactor is shown on the load side of the feeder circuit breaker and hence the feeder circuit breaker must have a suitable rating to interrupt the full available short-circuit current. In Figure 4(B) with the reactor on the bus side of the circuit breaker, economies could be realized in the feeder circuit breaker rating but the reactor represents an undesirable exposure of the bus and does not lend itself to good physical arrangement of the switchgear. Figure 4(C) shows a typical synchronizing bus arrangement with a reactor between the synchronizing bus and the generator bus. This arrangement gives a more direct path for flow of power from supply to load and provides a number of advantages over feeder reactors: lower kilowatt loss; lower kilovar loss; better voltage; permits low capacity feeder circuit breakers (low cost and less space); and usually fewer reactors and hence less space in the powerhouse.

GENERATOR AND LOAD DATA

CIRCUIT BREAKER RATING MVA \ SYSTEM KV	6.9	13.8
500	24000	25000

1500	40000	83000

Figure 6. Maximum capacity in kilovolt-amperes that may be connected to one bus in synchronizing bus arrangement

Figure 7. Use of a duplex reactor to divide the capacity of a large generator between two busses

Figure 8. Method of connecting to utility or other powerhouse

In the normal synchronizing bus arrangement best performance is obtained when the load requirements and generator capacity are fairly closely matched so that there is normally little power or reactive transfer across the reactance tie to the synchronizing bus.

In response to load changes, the no load voltage of the generator may be raised or lowered by action of its voltage regulator to maintain substantially constant voltage on the bus for all load conditions.

In the feeder reactor arrangement all current must pass through the reactor and some voltage variation will be experienced as the load magnitude and power factor vary. Wide fluctuations in load and the starting of large motors may make this a serious consideration for steel mills.

Figure 9. Circuit breakers connected directly to synchronizing bus

Figure 10. Geographical plan of typical steel mill areas

Synchronizing Bus

Figure 5 shows a synchronizing bus arrangement with three generators. While there are other methods of arranging reactance in a power system to limit short-circuit currents, such as the straight bus or ring bus with sectionalizing reactors, the synchronizing bus gives superior performance in almost every respect.

By far the outstanding advantage of the synchronizing bus arrangement is the unit simplicity or unit organization obtained for the system. This feature contributes the following benefits: ease of understanding, and ease of expanding the system.

In the synchronizing bus arrangement, each bus section is capable of operating as an independent unit, yet it is simply tied to a common bus where interchange of energy or reactive current can be accomplished. This arrangement is the simplest possible for the operator to understand and makes for good operating practices.

Once the pattern of a synchronizing bus is established, new busses can be added without greatly affecting the fault current on any of the existing busses. The fault current on the synchronizing bus is, of course, increased for each additional unit. In order to give the maximum flexibility for future expansion, it is usually desirable to make the momentary current rating of the bus considerably above that which is actually required for the installation as currently planned.

We now shall investigate some of the boundaries of application of a synchronizing bus arrangement with regard to system capacity and the capacity connected to each generator bus. We must first determine the approximate maximum amount of generating capacity that can be connected to each generator bus. A portion of this capacity might be a utility tie if the utility supply is the normal supply for the load connected to the bus. Figure 6 shows one arrangement with one generator on the bus and another with two equal size generators per bus. It is assumed that it would be undesirable to use a reactor in the tie to the synchronizing bus in excess of approximately 6 per cent based on maximum kilovolt-amperes expected to be transmitted through the reactor.

A multiple number of generators on the bus has the advantage that if one is out of service, a smaller amount of power and reactive current may be transmitted across the reactor and hence voltage under abnormal conditions will be better.

Shown in Figure 6 are tables giving the maximum permissible kilovolt-ampere capacity for 500, 1,000, and 1,500-megavolt-ampere circuit breakers. This in-

Table III. Generator Kilowatts Per Bus

Based on System Constants Per Figure 6

System Kilovolts / Circuit Breaker Interrupting Rating, Megavolt-Amperes	6.9	13.8	
500	20,000*	20,000	Use without feeder reactors
1,000	20,000*	40,000	Feeder reactors normally required
1,500	30,000	60,000	

* Capacity figures are rounded. Calculations gave 19,200 kw for 500 megavolt-ampere and 20,700 for 1,000 megavolt-ampere circuit breakers at 6.9 kv.

Figure 11 (left). Arrangement of high-voltage system

Figure 13 (above). Existing system to be expanded

formation is further summarized in Table III where the capacities have been converted to kilowatts. Approximately 20,000 kw is the maximum capacity that can be connected to one bus providing it is desired to use 500-megavolt-ampere circuit breakers on that bus and to avoid use of feeder reactors. Additional capacity can be connected to one bus providing larger circuit breakers are used and providing feeder reactors are added in the feeder or subdistribution circuits. There appears to be little advantage in using circuit breakers of 1,000 megavolt-amperes at 6,900 volts, and hence either 500-megavolt-ampere or 1,500-megavolt-amperes circuit breakers would be used at 6,900 volts. It should be recognized that heavy short-circuit currents at the 1,500-megavolt-ampere level at 6,900 volts may impose serious problems in keeping the thermal and mechanical ability of all parts of the system sufficiently high to withstand the short-circuit currents until they are cleared by the circuit breakers.

The maximum of 20,000 kw per generator bus does not imply that generators of larger than 20,000 kw could not be used with 500-megavolt-ampere switchgear. Figure 7 shows how the capacity of one generator may be divided between two busses by use of a duplex reactor.[4] However, it is doubtful if there are many requirements for this arrangement. Normally, higher voltage systems will be required when large generators are encountered and other arrangements will be adopted.

System Interconnections to Synchronizing Bus

In the synchronizing bus scheme it is usually desired to approximately balance the generating capacity with its corresponding load and normally there is little transfer through the reactor. Interconnections, such as a tie to an electrical utility or a tie to another power station, may not closely relate to any of the individual loads. Hence they should be connected to the synchronizing bus as shown in Figure 8. Circuit breakers are ordinarily required in order to protect the tie lines or tie transformers. Reactors are necessary to limit the fault current to the rating of the circuit breakers.

In some cases it may be desired to eliminate these reactors and connect larger circuit breakers directly to the synchronizing bus, Figure 9. Here a limit on the size to which the system can grow has been imposed by the rating of the circuit breakers connected to the synchronizing bus. Table IV gives the maximum system capacity that can be achieved without exceeding the rating of certain size circuit breakers when connected to the synchronizing bus. At a voltage of 13.8 kv or above and with 1,500-megavolt-ampere circuit breakers, a total system capacity of 200,000 kw can be achieved. At 6,900 volts the limit is 110,000 kw. For larger systems it would not be possible to connect circuit breakers directly to the synchronizing bus.

Choice of Voltage

In our discussion so far, we have described a system in which all of the system interconnections are accomplished at the generation and distribution voltage level. We have outlined the advantages of the synchronizing bus arrangement and have established the system capacity limits for using switchgear on the synchronizing bus. Also, we have obtained an understanding of the approximate amount of generating capacity that can be connected to each generator bus.

This information would be directly applicable to a system having approximately the geographical plan shown in Figure 10 for Area A. In this case the powerhouse is located close to the blast furnaces and all electric loads are in the same area. System voltage would be either 6,900 or 13,800. The 6,900-volt level would give the lower cost for the large motors. The 13,800-volt level would give lower cost for the distribution lines and switchgear (due to lower current). The higher voltage also permits use of circuit breakers directly connected to a synchronizing bus on larger systems than would be possible at 6,900 volts.

These factors must be evaluated for the

Figure 12. Method of connecting generators not supplying local loads

Figure 14. Method of expansion by subdivision of existing system and connection to synchronizing bus

Figure 15. Connection of low-voltage synchronizing bus to high-voltage system

particular plant to determine which voltage level should be adopted or whether the existing voltage level should be retained for the future expansion.

Need for Higher Voltages

Now suppose the steel mill comprises an additional area such as Area B similar to Area A and some distance away. Even though the generators at each area may be capable of supplying the load in that area, it may be desirable to tie the two systems together in order to reduce the total requirements for reserve capacity. The requirement for interconnecting the two powerhouses with transmission lines brings a desire for a higher voltage in order to reduce the cost and losses for the transmission line.

Let us add an additional area such as Area C to our steel plant and assume that this area incorporates only steel working capacity and hence is an electric load with no power-generating facilities. Now, the only way to supply this is by a transmission line and if the distance is great, there is a definite need for use of higher voltage for lower cost, lower losses, and lower voltage regulation.

Figure 11 shows a method of interconnecting the system at a higher system voltage with the synchronizing bus arrangement. Each generator bus is connected to the tie or synchronizing bus through a transformer. The tie to the other powerhouse, to the electrical utility, or to transmission lines to remote load areas would be connected directly to the high voltage synchronizing or tie bus. Studies have indicated that for most steel mills having need for a voltage above 6,900 or 13,800, a voltage of 33 kv should be adopted.

This voltage permits use of indoor station-type switchgear at almost the same cost as for 22 kv. Yet it gives lower cost for transmission lines. A higher voltage will require use of outdoor structures and usually will not give lower transmission line cost except for very large systems requiring transfer of appreciable power.

In some cases it may be desirable to adopt a utility transmission voltage where a tie is made to the utility, although this may mean an outdoor structure at higher than 33 kv and higher interrupting rating for switchgear.

At 33 kv with indoor-station type switchgear an interrupting rating of 1,500 megavolt-ampere will usually be best.

In some instances the power supply capacity at one of the powerhouses may considerably exceed the load in that area due to the availability of waste fuel. Generators not matched by local load should be connected directly to the high-voltage bus through transformers, as shown in Figure 12.

Expansion of Existing Systems

The arrangements which have been described may be used not only for new systems but also for modernization or expansion of existing systems. Figure 13, with a number of generators connected to a straight bus, is typical. The addition of new capacity may increase the short-circuit duty above the rating of the existing switchgear.

Table IV. Maximum System Generating Capacity in Kw for Circuit Breakers on Synchronizing Bus

System Kilovolts	6.9	13.8 or above
Circuit Breaker Rating, Megavolt-Amperes		
500	70,000	70,000
1,000	80,000	140,000
1,500	110,000	210,000

Calculation based on system shown by Figure 6.

Figure 14 shows how this existing system can be connected to a new synchronizing bus using the methods already prescribed. In this diagram the existing bus is divided into smaller busses with each bus individually connected to the new synchronizing bus through reactors. If the new system is to be at a higher voltage as dictated by economies of transmission lines, the synchronizing bus would be at the higher voltage and it would be necessary to install transformers in place of the reactors.

If the existing system is broken into a number of individual bus sections and each connected to a high-voltage system through transformers, the cost may be rather high for transformers and high-voltage switchgear. Where both the existing and the new high-voltage system have load and capacity that match and each has reserve capacity, it may be acceptable to form a low-voltage synchronizing bus and connect it to the high-voltage bus through a single transformer, as shown in Figure 15.

Discussion

S. Ein (Armco International Corporation, Chicago, Ill.): The matter contained in the paper can be used with considerable profit by power and steel mill engineers. The author has used an approach which is different from the usual one as far as the writer knows. The following discussion is not critical of the paper but is an elaboration of some points of interest to the writer.

It has been the writer's experience in several steel mills on which he had made many short-circuit studies that the proportion shown in Table I of the discussion exists between synchronous motors and generators.

Induction motors are not included by the writer in short-circuit studies. With few exceptions, the induction motors connected directly to the 13,800- and 6,900-volt busses discussed in the paper are wound-rotor motors. This type of motor operates with the external resistance of the slip regulator in the rotor circuit. Reports by one of the larger electrical motor manufacturers, based on tests, show that wound-rotor motors have

Table 1. Steel Mill Motors and Generators

Steel Mill	Synchronous Motors, Kva	Generation, Kva	Proportion, Per Cent
L*	57,100	108,700	53
R*	176,000	314,000	56
S**	57,700	93,800	62
Total	290,800	516,500	56
Paper			25

*L and R are very large steel mills now in existence and interconnected electrically.
**S is a small steel mill in the planning stage.

such a fast decrement that these motors can be neglected when momentary current is concerned.

This is not true where squirrel-cage induction motors are concerned if connected to the 13,800- and 6,900-volt busses. However, this type of motor is usually of such small size that if used at these voltages the cross-section of the coils becomes small and the coils will not withstand full-voltage starting and, in some cases, reduced-voltage starting. Therefore, the motors are used at 2,300 and 460 volts. This requires transformers which introduces reactance between the motors and the fault, and with the reactance of the lines on either side of the transformer, the momentary current is reduced to such an extent that neglect of the contribution of the motors to the fault causes only a comparatively small error when compared to the total duty. This reduction is partially compensated for by the increase in short-circuit kilovolt-amperes resulting from neglect of small reactances of short lines, busses, current transformers, and such minor items.

In short-circuit studies of motors conducted since 1935 in accordance with these considerations, the refinements described proved to be insufficient to affect choice of a circuit breaker size. Even if the result of a study shows a value slightly higher than that of the circuit breaker's rating, the next highest size of circuit breaker is not used, nor is a good plan changed. This action is correct because there is some inaccuracy in any set of values used; all of the equipment considered is rarely in service at one time, and it is a known fact that any circuit breaker rating is conservative. Taking advantage of these facts gives a practical result.

The synchronizing bus arrangement described in Figure 5 of the paper is of considerable interest to the writer. In the design for the new steel mill labeled *S* in Table I of the discussion, the original plan called for a continuous power station bus with 1,500,000-kva station-type circuit breakers and feeder reactors. The writer suggested a synchronizing bus which permitted the use of 500,000-kva metal-clad circuit breakers and eliminated the need for the feeder reactors. This latter plan, similar to Figure 5 of the paper, was adopted with a consequent prospective large monetary saving.

H. J. Finison: Mr. Ein's comments on the paper are very much appreciated. The availability of information on motor loads as supplied by Mr. Ein is very helpful for general systems studies of the type described in my paper. A discussion of the other comments by Mr. Ein follows.

In the study described in the paper, the subtransient reactance of induction motors was assumed to be 0.25 per unit which is higher than most high-speed induction motors. This assumption was made in order to allow for the effect of impedance of transformers and interconnecting cable for supplying 440- and 2,300-volt motors.

Since wound-rotor motors normally operate with most of the secondary resistance short-circuited out, they are essentially similar to squirrel-cage motors in their ability to contribute short-circuit current. Hence, they should be included in calculations for obtaining momentary short-circuit values.

For many types of electrical apparatus it has been common to assign continuous-duty ratings considerably lower than the maximum ability of the apparatus. However circuit breakers are maximum rated devices and should be applied only up to limits of their ratings. There appears to be excellent basis for such a rating method in that it permits the allocation of any safety margins by the person making the application.

Too often where ratings are not assigned at the maximum, safety margins may be adopted by both the designer and the system engineer. However, the system engineer must recognize his responsibility for not exceeding the maximum ratings assigned by the designer.

On low-voltage systems some reduction from calculated fault currents might be expected due to busses, connections, and so forth, which are not included in the calculation.

On high-voltage systems the effect of these will be relatively small, and it is possible that errors in data on machines and circuit impedance may be in a direction to give higher than calculated fault currents. Thus the system engineer can achieve true safety only by applying circuit protective equipment on systems where the available short-circuit current does not exceed the manufacturer's assigned ratings.

A 2-Channel Carrier Telegraph System for Short Submarine Cables

E. L. NEWELL
MEMBER AIEE

C. H. CRAMER
MEMBER AIEE

Synopsis: A new 2-channel carrier telegraph system for short submarine telegraph cables is described. Developed specifically for the Western Union Key West—Havana cables, about 100 nautical miles in length and with attenuations up to 80 decibels at 1,000 cycles per second, it utilizes standard land-line frequency-modulation channel terminal equipment and provides excellent 50-cycle telegraph transmission on both channels without appreciably degrading the physical circuits. Depending upon the facilities available the carrier may be operated either as a metallic or a ground-return circuit.

THE narrow useful frequency spectrum on submarine telegraph cables restricts the use of frequency-division methods of channelization. This is evident when it is noted that, of the transatlantic cables, the nonloaded types have attenuations of about 100 decibels at 15 to 20 cycles per second and the loaded cables have attenuations of the same order at 100 cycles. Where channelization is desirable on long cables use is made of electromechanical time-division multiplex methods.

The submarine telegraph cable network also includes cables of shorter lengths, ranging down to 100 nautical miles or less, which serve as connecting links in long circuits or provide direct traffic facilities such as those to or between islands. The connecting links originally were, and in some cases still are, operated at the speeds of the related long cable sections and thus below their potential signaling capacities. The direct facilities have been more fully developed under the compulsion of increasing traffic loads.

In recent years signal-shaping amplifiers have been installed rather generally on the connecting cables of some cable systems, making higher physical-circuit operating speeds available. As a result channels of separate long cables may be combined for transmission on the connecting links through use of modern time-division multiplex methods, involving devices such as the channel repeater.

Low frequency carrier circuits also are in use on a number of short cables in various cable systems. The limited use of carrier in the Western Union cable plant includes one early installation in which the cable is 326 nautical miles in length; the physical circuit can be operated at dot frequencies up to 30 cycles; the superposed circuit, in one direction only, with a carrier frequency of 90 cycles, is operated at a speed of 31 cycles. Another application of carrier, to which further reference is made in this paper, involves cables about 100 nautical miles in length and provides a 1-way channel with a carrier frequency of 300 cycles and an operating speed of 35 cycles.

Although the traffic requirements prevailing from time to time have been satisfied in the manner outlined previously, present utilization of the useful frequency spectrum of the short cables cannot be regarded as efficient. Consideration of means for attaining optimum efficiency inevitably leads to time-division multiplex methods. Because of mechanical limitations the multiplex system long in use on land-line and cable d-c telegraph circuits is not suitable for the high speeds implied. Perfection of electronic time-division systems, currently under intense development for radio applications, may well provide the ultimate solution at the bottom of the frequency spectrum also. In the meantime modern frequency-division methods and equipment, already in an advanced stage of development, are available and a recent carrier installation on the Western Union Key West—Havana cables has yielded a substantial increase in message capacity.

The Key West—Havana Cables

Western Union wire facilities to Cuba consist of three single-core submarine cables between Key West and Havana, each about 100 nautical miles in length. The physical circuits are operated as ground-return polar differential duplexes. Because of the high cable attenuation, the receiving terminals utilize the principle of the well-known Gulstadt vibrating relay to insure adequate sensitivity for the low-level received signals. The normal assignments are 3-channel multiplex circuits.

For some years the physicals were supplemented with two 1-way southbound carrier channels, each having a carrier frequency of 300 cycles per second and utilizing amplitude modulation. One channel was superposed on two of the cables as a metallic circuit, the second as a ground-return circuit on the third cable. The high attenuation of the cables and the state of the carrier art when the original system was installed made it impracticable to provide additional channels through the use of higher frequencies.

Recently a need for additional telegraph facilities to Cuba became evident. In view of improvements in carrier telegraphy it was decided to undertake the development of a new system which would provide two 2-way channels of higher transmission quality. The type *C-3* carrier system resulting from that development, and described in this paper, was installed at Key West and Havana in the early part of 1949.

Paper 50-10, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 19, 1949; made available for printing November 22, 1949.

Table I. Characteristics of Key West—Havana Cables

Cable	Length Nautical Miles	*Major Core Types	Total Resistance Ohms	Total Capacity Microfarads
2 KZ-HVA	105	107/140	988	31.2
3 KZ-HVA	98	160/166	675	35.2
4 KZ-HVA	96	130/130	775	30.5
Key West Undergrounds	0.89		23	0.15
Havana Undergrounds	4.44		70	2.0

* Pounds per nautical mile of copper and gutta percha.

Carrier System Requirements

When this project was initiated, traffic considerations required that the proposed carrier system should:

1. Provide two 2-way channels, each suitable for 35-cycle multiplex operation or for teleprinter operation.

2. Permit operation of the physical circuits as 3-channel multiplexes with the existing differential duplex equipment or as 4-channel multiplexes with resistance-bridge duplex circuits and signal-shaping amplifiers.

3. Be capable of operation as a metallic circuit over any two of the three cables, thus providing some protection against cable failure.

Cable Characteristics

The three Key West—Havana cables, *2, 3,* and *4 KZ-HVA*, are single-core, nonloaded cables lying about ten miles apart over most of their length. Each cable is a composite of several different types of cable. The general characteristics are given in Table I.

The receiving earth in all cases is carried back from the office through the underground to the cable hut at the beach on a conductor paired with the cable conductor.

The attenuation and impedance characteristics of the three cables, including the undergrounds, are shown in Figures 1 and 2. The attenuation characteristic of any two cables taken as a metallic circuit may be approximated by averaging the values of the selected cables. With attenuations of 38 to 46 decibels at 300 cycles, and 70 to 82 decibels at 1,000 cycles, these cables approach the attenuation characteristics of 16-gauge paper-lead cable. The total attenuation is about three times that encountered in a typical land-line carrier section. As a metallic circuit, the conductors of the submarine section are unbalanced and unpaired, conditions which, in a land-line carrier system, usually result in intolerable interference levels but are here largely offset by the shielding effect of the sea water.

Description of Carrier System

The *C-3* carrier system is shown schematically in Figure 3. It utilizes the frequency-modulation channel terminals[1] standardized by Western Union and widely installed in the land-line carrier systems.

The channel terminal comprises two units, one a sending-receiving filter panel, and the second a transceiver which combines the electronic transmitting and receiving functions. Standard mid-channel frequencies are used, 375 and 525

Figure 3. Block diagram of carrier system terminal

Figure 4 (left). Receiving filter characteristics

Figure 6 (right). Frequency characteristics of composites and antinoise sets

cycles for southbound transmission, and 825 and 975 cycles for northbound transmission. The channels have a bandwidth of 80 cycles and are spaced at 150-cycle intervals, with one channel omitted to facilitate directional separation. Frequency modulation of the transmitted carrier is accomplished by raising and lowering the mid-channel frequency 35 cycles to send spacing and marking impulses, respectively. This type of channel terminal is designed for operation at a maximum dot frequency of 35 cycles per second in land-line installations where two or more carrier systems may be operated in tandem. In such cases, the additive effects of successive channel filters narrow the channel bandwidth and thus limit the maximum signaling speed. The present application involves only a single carrier section and the channel bandwidth is sufficient under these conditions for a dot frequency of 50 cycles per second provided other factors, such as interference levels, are favorable.

Figure 5. System power levels

The channel terminals as used in the *C-3* system are standard in most respects. Minor wiring modifications in the transceivers adapt them to the power supplies at Key West and Havana and discard the half-duplex and repeater facilities which are not required in this instance. In the standard channel terminal, the sending and receiving channel carrier frequencies are alike while in the *C-3* system the sending and receiving frequencies differ.

Other components of the *C-3* system are: the hybrid coils which couple the carrier equipment to the cables, and the receiving amplifier, both of standard land-line type; sending amplifier, directional separation filters, impedance equalizer, antinoise set and composite, and leg circuit equipment, all of special design.

Directional separation of the channels is secured in part by frequency discrimination and to a lesser degree by the duplex balancing action of the hybrid coils. With different channel frequencies in the two directions, some directional discrimination is provided by the channel filters. The additional frequency discrimination required is obtained by the use of separation filters with cutoff in the 150-cycle guard band, located between the northbound and southbound channel frequencies. Characteristics of the channel receiving filters and the receiving separation filters are shown in Figure 4. The characteristics of the corresponding sending filters are generally similar. With cable attenuation up to 80 decibels, it is necessary to provide a total maximum discrimination of 110 decibels between sending and receiving channels to maintain crosstalk interference at 30 decibels below the received signal level. Under practical operating conditions, the discrimination resulting from the balanced hybrid coil arrangement may not be more than 10 decibels. The discrimination supplied by the channel filters amounts to about 80 decibels, nominally leaving 20 decibels to be provided by the separation filters. However, the channel filters do not protect the receiving amplifier, common to both channels, against overload by the sending frequencies and their modulation products. As shown in the system power level chart, Figure 5, the sending power level is high, about plus 38 decibels per channel or a total of 42 decibels (referred to zero power level of 1.0 milliwatt) and for that reason the separation filters must actually provide discrimination of some 60 decibels.

To provide the high sending carrier level, the transmitting amplifier has greater gain and power output than the corresponding amplifier standard in the land-line system. It consists of two push-pull stages, with three *25C6* tubes in parallel on each side of the output stage, and delivers 17 watts. By using about 20 decibels of combined voltage and current feedback, the total harmonic distortion is limited to one per cent and most of this is at frequencies outside the pass bands of the channel filters.

The cable capacitance combined with the capacitors used to couple the carrier system to the cables result in a highly reactive sending-end impedance at carrier frequencies. For efficient transfer of

carrier power to the cables, an impedance equalizer is used which provides a resistive load for the sending amplifier and filter, and matches the reactive cable input impedance.

The low carrier receiving levels and the small permissible degradation of the physical circuits impose severe requirements in the suppression of noise from the physical circuits. For this purpose use is made of antinoise sets and composites having the characteristics shown in Figure 6. The anti-noise sets are low-pass filters in the apexes of the physical circuits with cutoff at about 200 cycles and providing discrimination of over 60 decibels against carrier-frequency components of the physical circuit signals. The composites provide maximum discrimination against the physical circuit signals at the frequencies of the carrier channels. A total discrimination of over 100 decibels is thus obtained while the insertion loss in the physical circuits for frequencies below 150 cycles is less than three decibels. Corresponding values in land-line circuits are 50 decibels and 10 decibels.

High frequency noise components are generated by the motion of the armatures of the receiving relays of the physical circuits. This noise, unless suppressed, may overload the carrier receiving amplifier. The band-pass separation filter at Havana provides the necessary suppression, which, however, is lacking in the high-pass separation filter at Key West. At that terminal the suppression is accomplished by including in the composites an attenuation section centered at about 2,150 cycles.

In the land-line system, relays for transmitting and receiving have been eliminated in the channel terminals and the transceivers function entirely electronically with single-current telegraph impulses in the leg circuits. This simplification became practicable in the domestic telegraph plant with the vast expansion of carrier operation and the concurrent decline in d-c grounded and metallic facilities. Circuit extensions at Key West and Havana are not yet compatible with such simplification, and the *C-3* system includes intermediate relays in both the sending and receiving legs so that leg-circuit operation may be either single-current or polar. As shown in Figure 7, each leg circuit is provided with sounder and key and means for connecting a teleprinter for monitoring purposes. Jacks in the leg and intermediate relay circuits permit the insertion of a meter for measurements of current and signal bias.

While the *C-3* system is designed primarily for operation on a metallic circuit, it is evident that in the event of interruption of two of the three cables, ground-return operation on the remaining cable is greatly to be desired. Networks simulating the cable and artificial line impedances are provided at each terminal and arranged to be substituted for the second cable to maintain proper impedance relations for ground-return operation.

Figure 7 (above). Schematic of telegraph leg circuits

Figure 8 (right). Havana installation

At each terminal, all of the carrier equipment and the antinoise sets and composites are mounted on the two sides of a standard rack. Figure 8 shows the Havana installation.

Test and Performance Data

In Cuba, the submarine cables land at Cojimar and are extended to Havana in underground cable, a distance of 4.44 nautical miles, see Table I. The receiving earths are carried back to Cojimar, paired with the corresponding cable conductors. In this situation, satisfactory duplex balances for both the physical circuit and carrier frequencies could not be obtained with any normal adjustment of the Havana artificial lines. The difficulty was solved by inserting in the earth-return conductor at Cojimar a simple resistance-capacitance network which partially matches the impedance of the submarine cable section. Identical networks were installed for each cable. Under this condition, normal adjustments of the Havana artificial lines produce adequate balances at all significant frequencies. An additional advantage of the networks is that the cable and earth conductors of the underground section are more nearly balanced against extraneous interference. At Key West, where the undergrounds are short, no duplex balance problem was encountered.

With metallic circuit connections, the noise level from all sources at the input to the receiving side of the transceiver is 35 to 40 decibels below the received signal at Havana, and 40 to 45 decibels below the received signal at Key West, depending upon the combinations of cables used. With the carrier superposed on any two of the three cables, excellent margins are provided for teleprinter, 33-cycle polar ticker and 3-channel multiplex operation. With 50-cycle 3-channel multiplexes on both channels, the margins are better than those obtained on the physical circuits of the cables.

Set up as a ground-return circuit, the carrier noise level ranges from 30 to 40 decibels below the received signal at Havana, and 20 to 30 decibels below the received signal at Key West. Compared with Havana, the received signal level is low at Key West, since the northbound channels utilize the top frequencies and are more heavily attenuated; also noise from extraneous sources is higher because the cables are in shallow water for a greater distance at the Key West end of the route. The noise measurements were made during the month of February; somewhat higher levels of natural disturbances, such as lightning, may be ex-

pected during the summer months.

For the greater part of the year, ground-return operation on *3KZ-HVA* and *4KZ-HVA* provides excellent transmission quality on both carrier channels for teleprinter, ticker or 3-channel multiplex. Under similar conditions, *2 KZ-HVA* is less effective by reason of its higher attenuation. Some deterioration of ground-return operation during the summer months is caused by the lightning disturbances.

The performance of the new system in traffic service has amply confirmed the excellent test results. Since completion of the installation, there have been several cable interruptions. During one period, two of the cables were out of service.

Through use of the new carrier, all essential services to Cuba were maintained on the single remaining cable. On another occasion with one cable interrupted, the new system was superposed on one cable while an old-type 300-cycle channel was operated southbound on the second cable, with excellent performance of all facilities.

Traffic experience with ground-return operation of the new system has developed a special circuit arrangement of some practical importance. When a cable is out of service because of an interruption or fault, that cable, under favorable conditions, may be utilized with an operating cable to provide a regular metallic circuit connection for the carrier, thus retaining the low interference levels normal with metallic operation. The nature and location of the fault and its effect on the duplex balance of the faulty cable determine the suitability of this arrangement in specific situations. If the fault is so near to one terminal that the carrier duplex balance cannot be restored readily, the ground-return connection would be used for the carrier at that terminal while the metallic connection could be used at the distant terminal. If the fault is in the midsection of the cable the metallic connection can be utilized at both terminals.

Operation of the polar differential duplex physical circuits is not affected appreciably by the new carrier equipment The field tests indicate that 4-channel 66-cycle multiplex operation will be feasible as a resistance-bridge duplex with signal-shaping amplifiers.

The Key West—Havanac ables utilize core types, Table I, typical in general of short submarine telegraph cables. Although the *C-3* carrier system was developed for specific conditions it is applicable to similar cables for distances not exceeding about 100 nautical miles or attenuations not greater than 80 decibels at 1,000 cycles per second. Modified systems, such as one 2-way channel or one to four 1-way channels, would be suitable for cables of somewhat greater attenuation.

Control System Synthesis by Root Locus Method

WALTER R. EVANS
MEMBER AIEE

Synopsis: The root locus method determines all of the roots of the differential equation of a control system by a graphical plot which readily permits synthesis for desired transient response or frequency response. The base points for this plot on the complex plane are the zeros and poles of the open loop transfer function, which are readily available. The locus of roots is a plot of the values of s which make this transfer function equal to -1 as loop gain is increased from zero to infinity. The plot can be established in approximate form by inspection and the significant parts of the locus calculated accurately and quickly by use of a simple device. For multiple loop systems, one solves the innermost loop first, which then permits the next loop to be solved by another root locus plot. The resultant plot gives a complete picture of the system, which is particularly valuable for unusual systems or those which have wide variations in parameters.

THE root locus method is the result of an effort to determine the roots of the differential equation of a control system by using the concepts now associated with frequency response methods.[1] The roots are desired, of course, because they describe the natural response of the system. The simplifying feature of the control system problem is that the open loop transfer function is known as a product of terms. Each term, such as $1/(1+Ts)$, can be easily treated in the same manner as an admittance such as $1/(R+jx)$. It is treated as a vector in the sense used by electrical engineers in solving a-c circuits. The phase shift and attenuation of a signal of the form e^{st} being transmitted is represented by $1/(1+Ts)$ in which s in general is a complex number. The key idea in the root locus method is that the values of s which make transfer function around the loop equal to -1 are roots of the differential equation of the system.

The opening section in this paper, Background Theory, outlines the over-all pattern of analysis. The following section on Root Locus Plot points out the great usefulness of knowing factors of the open loop transfer function in finding the roots.

The graphical nature of the method requires that specific examples be used to demonstrate the method itself under the topics: Single Loop Example, Multiple Loop System, and Corrective Networks. The topic Correlation with Other Methods suggests methods by which experience in frequency methods can be extended to this method. The topic Other Applications includes the classic problem of solving an nth degree polynomial. Finally, the section on Graphical Calculations describes the key features of a plastic device called a "Spirule", which permits calculations to be made from direct measurement on the plot.

Background Theory

The over-all pattern of analysis can be outlined before explaining the technique of sketching a root locus plot. Thus consider the general single loop system shown in Figure 1.

Note that each transfer function is of the form $KG(s)$ in which K is a static gain constant and $G(s)$ is a function of the complex number. In general, $G(s)$ has both numerator and denominator known in factored form. The values of s which make the function zero or infinite can therefore be seen by inspection and are called zeros and poles respectively. The closed loop transfer function can be expressed directly from Figure 1 as given in equation 1

$$\frac{\theta_0}{\theta_i}(s)=\frac{K_\mu G_\mu(s)}{1+K_\mu G_\mu(s)K_\beta G_\beta(s)} \tag{1}$$

The problem of finding the roots of the differential equation here appears in the form of finding values of s which make the denominator zero. After these values are determined by the root locus method, the denominator can be expressed in factored form. The zeros of the function θ_0/θ_i can be seen from equation 1 to be the zeros of $G_\mu(s)$ and the poles of $G_\beta(s)$. The function can now be expressed as shown in equation 2

$$\frac{\theta_0}{\theta_i}(s)=K_c s^\gamma\frac{(1-s/q_1)(1-s/q_2)\ldots}{(1-s/r_1)(1-s/r_2)\ldots} \tag{2}$$

The constant K_c and the exponent γ depend upon the specific system but for control systems γ is often zero and K_c is often 1.

The full power of the Laplace Transform[2] or an equivalent method now can be used. The transient response of the output for a unit step input, for example, is given by equation 3

$$\theta_0(t)=1-\sum_{i=1}^{i=n}A_i e^{r_i t t} \tag{3}$$

The amplitude A_i is given by equation 4

$$A_i=\left[\frac{\theta_0}{\theta_i}(s)(1-s/r_i)\right]_{s=r_i} \tag{4}$$

The closed loop frequency response, on the other hand, can be obtained by substituting $s=j\omega$ into equation 2. Fortunately, the calculation in finding A_i or $\theta_0/\theta_i(j\omega)$ involves the same problem of multiplying vectors that arises in making a root locus plot, and can be calculated quickly from the resultant root locus plot.

Paper 50-11, recommended by the AIEE Feedback-Control Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 15, 1948; made available for printing November 22, 1949.

WALTER R. EVANS is with North American Aviation, Inc., Downey, Calif.

The author wishes to express his appreciation for the assistance given by his fellow workers, K. R. Jackson and R. M. Osborn, in the preparation of this paper. In particular, Mr. Osborn contributed the circuit analysis example.

Figure 1 (left). General block diagram

Figure 3 (right). Single loop root locus

Root Locus Plot

The open loop transfer function is typically of the form given in equation 5.

$$K_\mu G_\mu(s) K_\beta G_\beta(s) = \frac{K(1+T_2 s)[\sigma_3^2+\omega_3^2]}{s(1+T_1 s)[(s+\sigma_1)^2+\omega_1^2]} \quad (5)$$

The parameters such as T_1 are constant for a given problem, whereas s assumes many values; therefore, it is convenient to convert equation 5 to the form of equation 6.

$$K_\mu G_\mu(s) K_\beta G_\beta(s) = \frac{K(1/T_1+s)T_2[\sigma_3^2+\omega_3^2]}{s(1/T_1+s)T_1[(s+\sigma_3+j\omega_3)(s+\sigma_3-j\omega_3)]} \quad (6)$$

The poles and zeros of the function are plotted and a general value of s is assumed as shown in Figure 2.

Note that poles are represented as dots, and zeros as crosses. All of the complex terms involved in equation 6 are represented by vectors with heads at the general point s and tails at the zeros or poles. The angle of each vector is measured with respect to a line parallel to the positive real axis. The magnitude of each vector is simply its length on the plot.

In seeking to find the values of s which make the open loop function equal to -1, the value -1 is considered as a vector whose angle is 180 degrees $\pm n$ 360 degrees, where n is an integer, and whose magnitude is unity. Then one can consider first the problem of finding the locus of values for which the angle condition alone is satisfied. In general, one pictures the exploratory s point at various positions on the plane, and imagines the lines from the poles and zeros to be constructed

Figure 2. Root locus plot

so that the angles in turn can be visualized. For any specific problem, however, many special parts of the locus are established by inspection as illustrated in examples in later sections. Surprisingly few trial positions of the s point need be assumed to permit the complete locus to be sketched.

After the locus has been determined, one considers the second condition for a root, that is, that the magnitude of $K_\mu G_\mu(s) K_\beta G_\beta(s)$ be unity. In general, one selects a particular value of s along the locus, estimates the lengths of the vectors, and calculates the static gain $K_\mu K_\beta = 1/G_\mu(s) G_\beta(s)$. After acquiring some experience, one usually can select the desired position of a dominant root to determine the allowable loop gain. The position of roots along other parts of the locus usually can be determined with less than two trials each.

An interesting fact to note from equation 6 is that for very low gain, the roots are very close to the poles in order that corresponding vectors be very small. For very high gain, the roots approach infinity or terminate on a zero.

Single Loop Example

Consider a single loop system such as shown in Figure 1 in which the transfer functions are given in equation 7.

$$K_\mu G_\mu(s) = \frac{K}{(1+T_1 s)(1+T_2 s)s}; K_\beta G_\beta(s) = 1 \quad (7)$$

The poles of the open loop function are at 0, $-1/T_1$ and $-1/T_2$ as represented by dots in Figure 3.

The locus along the real axis is determined by inspection because all of the angles are either 0 degrees or 180 degrees. An odd number of angles must therefore be 180 degrees as shown by the intervals between 0 and $-1/T_1$, and from $-1/T_2$ to $-\infty$. Along the $j\omega$ axis, ϕ_0 is 90 degrees so that ϕ_2 must be the complement of ϕ_1, as estimated at $s=j\omega_c$. For very large values of s, all angles are essentially equal so the locus for the complex roots finally approaches radial lines at ± 60 degrees.

The point where the locus breaks away from the real axis is found by considering a value of s just above the real axis. The decrease in ϕ_0 from 180 degrees can be made equal to the sum of ϕ_1 and ϕ_2 if the reciprocal of the length from the trial point to the origin is equal to the sum of the reciprocals of lengths from the trial point to $-1/T_1$ and $-1/T_2$. If a damping ratio of 0.5 for the complex roots is desired, the roots r_1 and r_2 are fixed by the intersection with the locus of radial lines at ± 60 degrees with respect to negative real axis.

In calculating K for $s=r_1$, it is convenient to consider a term $(1+T_1 s)$ as a ratio of lengths from the pole $-1/T_1$ to the s point and from s to the origin respectively. After making gain $K=1/[G(s)]_{s=r_1}$ a good first trial for finding r_3 is to assume that it is near $-1/T_2$ and solve for $(1/T_2+s)$. After the roots are determined to the desired accuracy, the over-all transfer function can be expressed as given in equation 8.

$$\frac{\theta_o}{\theta_i} = \frac{1}{\left(1-\frac{s}{r_1}\right)\left(1-\frac{s}{r_2}\right)\left(1-\frac{s}{r_3}\right)} \quad (8)$$

The procedure in handling a multiple loop system now can be explained.

Multiple Loop System

Consider a multiple loop system in which the single loop system just solved is the forward path of another loop, as shown in Figure 4.

θ_o/θ_i is given in factored form by equation 8 so the roots of the inner loop now serve as base points for the new locus plot. For convenience, however, neglect the effect of the term $(1-s/r_3)$ so that the locus for the outer loop is shown in Figure 5.

The locus for the outer loop would be a circle about the $-1/T$ point as a center if the effect of θ_o/θ_i were completely neglected. Actually, the vectors from the points r_1 and r_2 introduce net angles so that the locus is modified as shown. The

Figure 4 (above). Multiple loop block diagram

Figure 5 (right). Multiple loop root locus

angle at which the locus emerges from r_1 can be found by considering a value of s close to the point r_1, and solving for the angle of the vector $(s-r_1)$.

Assume that the static loop gain desired is higher than that allowed by the given system. The first modification suggested by the plot is to move the r_1 and r_2 points farther to the left by obtaining greater damping in the inner loop. If these points are moved far to the left, the loci from these points terminate in the negative real axis and the loci from the origin curve back and cross the $j\omega$ axis. Moving the $-1/T$ point closer to the origin would then be effective in permitting still higher loop gain. The next aspect of synthesis involves adding corrective networks.

Corrective Networks

Consider a somewhat unusual system which arises in instrument servos whose open loop transfer function is identified by the poles p_1 and p_2 in Figure 6(A). As loop gain is increased from zero, the roots which start from p_1 and p_2 move directly toward the unstable half plane. These roots could be made to move away from the $j\omega$ axis if 180 degrees phase shift were added. A simple network to add is three lag networks in series, each having a time constant T such that 60 degrees phase shift is introduced at p_1. The resultant locus plot is shown in Figure 6(B).

The gain now is limited only by the requirement that the new pair of roots do not cross the $j\omega$ axis. A value of gain is selected to obtain critical damping of these roots and the corresponding positions of all the roots are shown in Figures 6(A) and 6(B) as small circles.

Actually, greater damping could be achieved for roots which originate at p_1 and p_2 if a phase shifting bridge were used rather than the 3-lag networks. Its transfer function is $(3-Ts)/(1+Ts)$ and is of the "nonminimum phase" type of circuit.

Since these types of correction are somewhat unusual, it is perhaps well to point out that the analysis has been verified by actual test and application.

These examples serve to indicate the reasoning process in synthesizing a control system by root locus method. An engineer draws upon all of his experience, however, in seeking to improve a given system; therefore, it is well to indicate the correlation between this method and other methods.

Correlation with Other Methods

The valuable concepts of frequency response methods[1] are in a sense merely extended by the root locus system. Thus a transfer function with s having a complex value rather than just a pure imaginary value corresponds to a damped sinusoid being transmitted rather than an undamped one. The frequency and gain for which the Nyquist plot passes through the -1 point are exactly the same values for which the root locus crosses the $j\omega$ axis. Many other correlations appear in solving a single problem by both methods.

The results of root locus analysis can be easily converted to frequency response data. Thus one merely assumes values of s along the $j\omega$ axis, estimates the phase angles and vector lengths to the zeros and poles, and calculates the sum of the angles for total phase shift and the product of lengths for attenuation. The inverse problem of determining zeros and poles from experimental data is the more difficult one. Many techniques are already available, however, such as drawing asymptotes to the logarithmic attenuation curve. For unusual cases, particularly those in which resonant peaks are involved, the conformal mapping technique originated by Dr. Profos of Switzerland is recommended.[3]

The transient response is described by the poles of the transfer function. The inverse problem in this case is to locate the poles from an experimental transient response. One might use dead time, maximum build-up rate, overshoot, natural frequency of oscillation, and the damping rate as effective clues in solving this problem.

Other Applications

Many systems require a set of simultaneous equations to describe them and are said to be multicoupled. The corresponding block diagrams have several inputs to each loop so that the root locus method cannot be applied immediately. One should first lay out the diagram so that the main line of action of the signals forms the main loop with incidental coupling effects appearing as feedbacks and feed forwards. One then proceeds to isolate loops by replacing a signal which comes from within a loop by an equivalent signal at the output, replacing a signal entering a loop by an equivalent signal at the input. One can and should keep the physical picture of the equivalent system in mind as these manipulations are carried out.

The techniques of the root locus method can be used effectively in analyzing electric circuits. As a simple example, consider the lead-lag network of Figure 7(A).

It can be shown that the transfer function of this network is as given in equation 9

$$\frac{V_0}{V_i}=\frac{(1+R_1C_1s)(1+R_3C_3s)R_3}{(1+R_1C_1s)(1+R_3C_3s)R_3+R_1[1+(R_3+R_3)C_3s]} \tag{9}$$

The denominator can be factored algebraically by multiplying out and finding the zeros of the resulting quadratic. As an alternative, it will be noted that the zeros of the denominator must satisfy equation 10

Figure 6. (A) Basic system. (B) Corrected system

Figure 7 (left). (A) Circuit diagram. (B) Root locus

Figure 8 (right). Spirule

$$\frac{(1/R_1C_1+s)(1/R_2C_2+s)R_3(R_1C_1)(R_2C_2)}{[1/(R_2+R_3)C_2+s](R_2+R_3)C_2R_1} = -1 \quad (10)$$

The vectors in this expression are represented according to the root locus scheme in Figure 7(B). The two roots are thereby bounded as shown by the two dots and the cross. Their exact locations could be estimated or accurately determined by graphical methods.

The locus of roots now is simply intervals along the negative real axis between the open loop zeros and poles as shown in Figure 7 (B). The exact location of the roots along these intervals is determined in the usual way. Note that the constant in equation 10 is of the form $R'C_1$, in which R' is the effective value of R_2 and R_3 in parallel.

In more complicated networks, the advantages of the root locus concept over algebraic methods becomes greater; its particular advantage is in retaining at all times a clear picture of the relationships between the over-all network parameters and the parameters of individual circuit elements.

In the classical problem of finding roots, the differential equation is given in the form of a sum of terms of successively higher order. This can be converted to the form shown in equation 10

$$s^n+as^{n-1}+bs^{n-2}+\ldots+m = [(s+a)s+b]s+\ldots+m \quad (11)$$

This corresponds to a block diagram with another loop closed for each higher order term. Solve for the roots of the first loop which corresponds to the quantities in brackets above and proceed as before for the multiple loop system. If the roots close to the origin are of most interest, substitute $s=1/x$ first and solve for root values of x. Other combinations are, of course, possible because a single root locus basically determines the factors of the sum of two terms.

The root locus method is thus an analytical tool which can be applied to other problems than control system synthesis for which it was developed. But in attacking a new problem one would probably do well to try first to develop a method of analysis which is natural for that problem rather than seek to apply any existing methods.

Graphical Calculations

The root locus plot is first established in approximate form by inspection. Any significant point on the locus then can be checked by using the techniques indicated in this section. Note that only two calculations are involved, adding angles and multiplying lengths. Fortunately, all of these angles and lengths can be measured at the s point. Thus angles previously pictured at the zeros and poles also appear at the s point but between a horizontal line to the left and lines to the zeros and poles. A piece of transparent paper or plastic pivoted at the s point can be rotated successively through each of these angles to obtain their sum.

The reader can duplicate the "spirule" with two pieces of transparent paper, one for the disk and the other for the arm. Several procedures are possible, but the over-all purpose is to successively rotate the arm with respect to the disk through each of the angles of interest. Thus for adding phase angles, the disk is held fixed while the arm is rotated from a pole to the horizontal, whereas the two move together in getting aligned on the next pole. For multiplying lengths, the disk is held fixed while the arm is rotated from the position where a pole is on the straight line to the position where the pole is on the logarithmic curve. Rotations are made in the opposite directions for zeros than they are for poles.

Conclusions

The definite opinion of engineers using this method is that its prime advantage is the complete picture of a system which the root locus plot presents. Changing an open loop parameter merely shifts a point and modifies the locus. By means of the root locus method, all of the zeros and poles of the over-all function can be determined.

Any linear system is completely defined by this determination, and its response to any particular input function can be determined readily by standard mathematical or graphical methods.

High-Voltage Oil Circuit Breakers for 5,000,000- to 10,000,000-Kva Interrupting Capacity

W. M. LEEDS
FELLOW AIEE

R. E. FRIEDRICH
ASSOCIATE AIEE

ONLY a few years ago, 3,500,000 kva was the maximum standard rated interrupting capacity for high-voltage circuit breakers, and the interrupting time ratings were mostly five and eight cycles. This paper describes recent developments in interrupting devices that have made available standard circuit breakers for 5,000,000-kva interrupting capacity and 3-cycle interrupting time for 138-, 161-, and 230-kv voltage classes. Particular attention is directed to the circuit breakers recently shipped to the 230-kv switchyard at Grand Coulee Dam which carry a 10,000,000-kva interrupting capacity rating on a 20-cycle reclosing duty cycle.

At the 1945 AIEE Winter Meeting, a paper was presented entitled The Next Step in Interrupting Capacity—5,000,000 Kva by A. W. Hill and W. M. Leeds,[1] which predicted that the growing needs of the electrical industry would soon require high-voltage circuit breakers having interrupting capacity in excess of the then maximum available rating of 3,500,000 kva. The development work by one manufacturer along this line was described, and test data were submitted to demonstrate the feasibility of designing higher capacity circuit breakers when required. Furthermore, the possibility of providing circuit breakers capable of operating on rapid reclosing duty with time intervals substantially shorter than 20 cycles was indicated.

The predictions of 1945 as to the future demand for high-voltage circuit breakers have been more than fulfilled, with circuit breakers now being built for not only 5,000,000 kva but as high as 10,000,000 kva, and even higher capacity being given consideration. Recognition of these growing demands for higher interrupting capacity is indicated by the American Standards Association (ASA) Preferred Ratings for Power Circuit Breakers,[2] which lists 5,000,000-kva ratings for 3-cycle oil circuit breakers in the 138-, 161-, and 230-kv voltage classes. Further evidence that this demand is not confined to one or two specific locations can be gained by considering the various places where high-power circuit breakers having 5,000,000-kva interrupting capacity or higher are actually being installed: 230-kv 10,000,000-kva circuit breakers for both Grand Coulee Dam and Hoover Dam; 230 kv 5,000,000 kva at 25-cycle frequency for the Hydro Electric Commission of Ontario; 230 kv, 5,000,000 kva at 50-cycle frequency for Electricité de France; 161 kv, 5,000,000 kva for the Aluminum Company of America in Tennessee; and 138 kv, 5,000,000 kva for the Ohio Power Company and Consolidated Edison Company of New York. These installations comprise 76 complete 3-pole circuit breakers from one manufacturer and its Canadian affiliate alone, representing an investment of between $4,000,000 and $5,000,000, with an appreciable number of additional high-power circuit breakers being built by other manufacturers for these and other power systems such as the Pacific Gas and Electric Company and the Bonneville Power Administration. The specifications for many of these circuit breakers provide that they shall be capable of performing on rapid reclosing duty.

The paper describes some of the special design features for steel-tank oil circuit breakers rated 5,000,000 kva at 138 kv, 161 kv, and 230 kv, and rated 7,500,000 or 10,000,000 kva at 230 kv. The method of verifying these interrupting capacities both in the manufacturers' high-power laboratory and by field tests on a customer's property is outlined, with special consideration given to the problems of switching line-charging currents and of interrupting high power repeatedly, under both standard duty and rapid reclosing duty cycles.

Types of High-Power Circuit Breakers

High-power circuit breakers for use at transmission voltages can be designed along at least three different lines. These three types may be classified as compressed air (air-insulated porcelain columns with air-blast arc interruption), low-oil-content (oil-insulated porcelain columns with oil-flow arc interruption), and steel-tank circuit breakers (oil insulation and oil-flow arc interruption). Compressed-air circuit breakers have found wide acceptance in European countries, although interrupting capacities do not approach 5,000,000 kva, and few, if any, circuit breakers have interrupting time ratings as short as the present American standard of 3 cycles or 0.05 second. A number of 138-kv and 230-kv air-blast circuit breakers are in operation in Canada, and there are two limited installations of 138-kv compressed-air circuit breakers in the United States.[3,4] A series of interrupting tests was made two years ago on the Bonneville Power Administration 230-kv system with a compressed-air circuit breaker manufactured before 1939 in Germany, rated 2,500,000 kva at 220 kv.[5] The tests indicated excellent fault-interrupting ability but unsatisfactory

Paper 50-12, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing November 22, 1949.

W. M. Leeds and R. E. Friedrich are both with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. 230-kv 3-cycle oil circuit breakers at Columbia substation on the Bonneville Power Administration System

operation when clearing line-charging current. Still more effective air-blast circuit breakers have been designed and built for 230-kv and others are in process of development. However, the high-power compressed-air circuit breaker capable of a 3-cycle interrupting time rating in an adequately insulated structure for outdoor service, when considered together with necessary auxiliaries, does not appear at the present time to be competitive in cost with the most modern oil circuit breaker types.

The low-oil-content, or porcelain-clad type of circuit breaker designed for minimum oil volume, also has had considerable success in Europe, where interrupting time and arc-rupturing capacity requirements are not as severe as in this country. In the United States the most successful type of high-speed heavy-duty porcelain-clad circuit breaker is the so-called "impulse circuit breaker." The design and performance of this circuit breaker has been described several times before the institute.[6] While the interrupting performance on both line-charging currents and heavy faults leaves little to be desired, the need for separate current transformers, either porcelain-clad wound-type or the conventional through-type mounted on separate bushings independent of the circuit breakers, plus the extremely powerful operating mechanism required, in comparison with that used on conventional steel-tank circuit breakers, tend to make the impulse circuit breaker a rather costly device.

The steel-tank circuit breaker, Figure 1, has undergone continuous development during the past 30 years, taking in its stride a reduction in interrupting time from 25 cycles to 3 cycles, and an increase in interrupting capacity from one to 10,000,000 kva with a simultaneous reduction in physical dimensions. The availability of high-power laboratories has accelerated the design of more and more effective types of arc-extinguishing devices. Field tests, particularly those which provide short-circuit power in excess of that available in the laboratories, have been particularly helpful in verifying extensions of circuit breaker interrupting capacity into the higher ratings beyond 3,500,000 kva.

A group of three papers was presented at the 1948 AIEE Winter Meeting in Pittsburgh,[7,8,9] describing the design features, laboratory, and field performance of extra-heavy interrupting capacity circuit breakers being developed for 230-kv 3-cycle performance. It was concluded, at that time, that circuit breakers for use at Grand Coulee Dam, up to 10,000,000 kva, were entirely feasible. In the paper by Leeds and Cushing,[7] the elements of a steel-tank circuit breaker for heavy-duty interruption at high speed were outlined. Because of the relatively small amount of gas associated with the interruption of high-power arcs using modern interrupting devices, the tank diameter and clearances between live parts and ground are dictated almost entirely by the requirements of the standard 1-minute insulation test. At the present time, the minimum tank diameters appear to be in the neighborhood of 54 inches for 138 kv, 62 inches for 161 kv and 78 inches for 230/196 kv. The dimensions of the highest power interrupter assemblies make it necessary, in some cases, to increase these minimum diameters slightly.

Since the more conventional features of a heavy-duty high-speed steel-tank circuit breaker, such as oil-impregnated bushings and pneumatic operating mechanism, were adequately described in the earlier paper, this discussion will emphasize primarily the special design improvements, particularly in the interrupter assemblies, which have been developed recently to increase the speed of operation and maximum rupturing capacity on both standard and high-speed reclosing duty.

Design Features of a Heavy-Duty Multiflow Interrupter

The view in Figure 2, through the manhole of a 230-kv 10,000,000-kva circuit breaker, shows the location of a pair of heavy-duty multiflow "De-ion" grid contact assemblies for one circuit breaker pole. Only one interrupting unit per terminal is required, even for a 3-cycle interrupting time, because of the exceptional effectiveness of the arc-extinguishing elements. The aluminum moving contact bridges the two contact assemblies when raised to the closed position by the insulated lift rod.

Figure 2. View of the multiflow grid interrupters inside one pole of a 230-kv 3-cycle circuit breaker rated 10,000,000 kva

The relative size of three different contact assemblies for 5,000,000 kva at 138, 161, and 230 kv as well as the 10,000,000-kva 230-kv assembly, is shown in Figure 3. It should be noted that these interrupters differ primarily only in physical dimensions, since the functioning is substantially the same for each rating. Figure 4 shows the 230-kv 10,000,000-kva interrupter in schematic cross section, and illustrates the essential functions of the several assemblies. The 3-cycle grid resembles the 5-cycle type of multiflow De-ion grid in operation, but has the additional feature of an oil-driving pump which augments the flow from the pressure-generating break at low magnetizing

Figure 3. Heavy-duty 3-cycle multiflow grids rated 138, 161, and 230 kv at 5,000,000 kva, and 230 kv at 10,000,000 kva

and line-charging currents. By this means, flat 3-cycle interrupting time is obtained for all values of current which the circuit breaker may be called on to interrupt. At higher currents, where the pressure produced is greater than that obtainable from the piston, the piston does not operate until after arc interruption occurs, and then serves to flush residue arc products from the grid. This function is of particular value on high-speed reclosing where it is desirable to clean out the gases remaining from the first interruption before the circuit breaker may be called on to open the circuit a second time within 20 cycles or less. For the interruption of line-charging currents where it is desirable to avoid arc restrikes that develop over-voltage surges, the oil-piston action is purposely delayed so that interruption will be attempted only after the contacts have parted sufficiently to be able to support the double voltage that appears one-half cycle later.

An important new feature is the arrangement by which the intermediate contact is spring-biased upwards and is free to move for one-half inch from the closed position. During an opening operation, the intermediate contact moves upwards for this distance, together with the tip on the rocker contact. At the same time, the lower contact is accelerated downward so that the interrupting gap is formed at a speed nearly three times that of the moving cross-member during the first quarter-inch of circuit breaker lift-rod travel. This feature makes it possible to eliminate multiplying levers between the lower contact and cross arm, and with only a slight increase in lift-rod speed the desired high-speed interrupting time and no-restrike performance on line-charging currents is obtained. The fact that the formation of the upper pressure-generating gap is delayed by this arrangement makes it possible to interrupt

Figure 4. Cross section of 230-kv 10,000,000-kva multiflow grid

Light arrows indicate path of oil flow from piston *A*, augmenting flow (heavy arrows) from pressure-generating arc *B* to interrupting section *C*. When circuit breaker is tripped, cross member *D* moves down, followed by contact *E* and collar *F*, which collar picks up piston after short delay to provide time for adequate contact separation for charging current interruption without restriking. Intermediate contact *G* is biased upward, following rocker contact *H* for short distance. Contact *H* is rotated to open position through links *I* and contact loading spring *J* by means of operating rod *K*. Oil dashpot *L* opposes extension of spring *J*, speeding opening of contact *H*, but closing action is free due to check valve *M*. Lower contact *E* is stopped on shoulder *N*, allowing crossarm *D* to pull out of fingers *O* to form isolating gap after arc extinction. Vents *R* from interrupting section *C* are separated from oil channels by orifice plates *Q*

Figure 5. Comparative speed of contact gap opening in different types of interrupters

A—230-kv 5-cycle 2,500,000-kva multiflow grid
B—230-kv 3-cycle 5,000,000-kva multiflow grid
C—230-kv 3-cycle 10,000,000-kva multiflow grid

Figure 6. Timing test showing 8.7-cycle reclosing time on 3-pole oil circuit breaker rated 230 kv 10,000,000 kva

higher power, since excessive pressure is not built up waiting for a sufficient contact separation for arc interruption in the main contact gap.

An oil dashpot arrangement is incorporated into the upper end of the grid operating rod and is designed so as to delay relative motion between the rod and links attached to the rocker contact. This is made operative during an opening operation only, using a spring-biased check valve. Thus, during normal rapid opening of the contacts, the rocker contact begins to rotate upwards, allowing the intermediate contact to lift as soon as the moving cross-member moves downward, thus affording further savings in interrupting time.

A comparison of the relative positions of the pressure-generating and interrupting breaks is shown in the diagram of Figure 5 for (A) the older 5-cycle type of grid without piston, (B) the new grid with piston for applications up to 230 kv 5,000,000 kva, and (C) the 230 kv 10,000,000 kva with the dashpot arrangement on the operating rod. Successive contact positions are shown for (1) the circuit breaker closed, and (2) (3) after one-half and one-inch travel of the main moving cross-member attached to the circuit breaker lift rod. The greatest gap length for a given circuit breaker travel is obtained by the upward lifting intermediate contact and operating-rod dashpot combination in Figure 5(C).

After the lower grid contact is spring-driven to its open position against a stop, further travel of the moving cross-member forms a disconnect gap below the interrupter. This gap serves to remove voltage from the grid assembly while the circuit breaker stands in the open position, and also interrupts the small fraction of an ampere drawn by the voltage-dividing resistors which are provided to make sure that each interrupter handles its proper share of the recovery voltage.

The use of butt-type contacts with silver-tungsten arcing tips is retained because of the inherent high-speed opening obtained in comparison with finger-type contacts. Since the momentary current-carrying capacity of the contacts for these heavy-duty circuit breakers must be as high as 40,000 amperes, tests have been made to determine the amount of spring-loading required to assure the ability to handle this large amount of current without welding or excessive pitting of the contacts. Adequate heat conduction away from the sources of heat generation is provided to pass a 25,000 ampere current-carrying test for the rated 4-second period, and to carry continuously loads as high as 1,200 amperes without excessive temperature rise. An undesirable additional heat source from the helical springs surrounding the grid contacts is avoided by using nonmagnetic stainless steel for these items.

Circuit Breaker Operating Speeds

The interrupting time of a circuit breaker includes three steps: (1) the time from energizing the trip coil until the circuit breaker mechanism is unlatched; (2) the mechanical time required to separate the circuit breaker contacts;

Figure 7. High-power laboratory tests on 230-kv 10,000,000-kva circuit breaker

C—66-kv damped transient on Grand Coulee circuit with asymmetrical short-circuit current of 18,200 amperes

Figure 9. Oscillogram of 13.5-cycle reclosing duty test on 230-kv 10,000,000-kva circuit breaker opening 20,700 amperes at 44 kv across a half-pole unit equivalent to a 3-phase fault of 8,250,000 kva at 230 kv

Figure 10. Oscillogram of 9.5-cycle reclosing duty test on 230-kv 10,000,000-kva circuit breaker opening 15,900 amperes at 66 kv across a half-pole unit equivalent to a 3-phase fault of 6,330,000 kva at 230 kv

and (3) the arcing time. While the first two steps take a fairly constant time interval, the arcing period is affected by the random occurrence of current zero with respect to the parting of the contacts so that a variation of at least one-half cycle in the arcing time, and therefore, in the total interrupting time, is inevitable. A typical timing test on a tripping operation of the 230-kv 10,000,000-kva 3-cycle circuit breaker shows 0.6 cycle to unlatch, 0.6 cycle to part contacts after unlatching, and an arcing time of 0.8 to 1.3 on fault interruptions, giving a total interrupting time of 2.0 to 2.5 cycles.

The closing time from energizing the electrically-operated air valve until the contacts touch requires only about 18 cycles, of which one and one-half cycles represents the time to get the inlet valve open and high pressure air on the piston of the pneumatic operating mechanism. A specially designed large-size air inlet valve with a 2-inch diameter port, together with a 2-inch flexible hose connection, is provided for the 10,000,000-kva circuit breaker to keep the cylinder pressure close to that in the air reservoir during a closing operation.

A normal 20-cycle reclosing operation is obtained by energizing the closing contactor from a 2-pole switch on the operating mechanism which makes up its contacts when the circuit breaker has opened about halfway. The air pressure admitted to the main cylinder brings the circuit breaker to rest a little short of the full open position, reverses the movement quickly and sends the circuit breaker back to the closed position. By advancing the position at which the 2-pole switch initiates the closing function, the reclosing time interval, measured from energizing the trip coil to the instant when the contacts touch on reclosure, may be reduced to as short as 12 cycles. By a reconnection of the control circuit so that the closing valve is energized directly by the 2-pole switch, reclosing times as short as 9 cycles, Figure 6, have been obtained on the 230-kv 3-pole circuit breaker operated by a single pneumatic mechanism. Insulator flashover deionization has been found to take from 10 to 16 cycles after fault interruption in the 3,500,000- to 10,000,000-kva range at 230 kv,[10,11] so that practical reclosing time intervals for 3-cycle circuit breakers at this voltage appear to be limited to not less than 15 cycles. However, it is evident that faster reclosing can be made available if the need should arise.

Demonstration of High-Power Interrupting Capacity

The limitations of high-power laboratory test power usually make it necessary to do most of the testing on a single-pole unit instead of making full 3-phase fault interrupting tests. Quoting from the ASA Test Code for Power Circuit Breakers, paragraph 9-1.2.4,[12] "the voltage to be used in making single-pole tests is determined by the manufacturer, because he is responsible for the adequacy of the voltage used to demonstrate the ability of a circuit breaker to meet its rating." Even with effectively-grounded systems, 3-phase ungrounded faults can occur, for instance, as a result of a steel cable being dragged by an airplane across all three phases of a transmission line, so that the condition of 87 per cent of line voltage across the first pole to clear must be considered as a possibility.

Another abnormal voltage condition may occur during transient instability when two parts of a system swing out of synchronism so that a tie circuit breaker could be called upon to interrupt practically double normal line-to-ground voltage across terminals, equivalent to approximately 115 per cent of line-to-line voltage across a single pole. For these reasons, it is considered desirable to demonstrate adequate voltage-interrupting ability of a high-voltage circuit breaker by including single-phase interrupting tests opening reasonable amounts of power, up to perhaps 25 per cent of the current interrupting capacity, with voltages as high as twice normal line-to-ground potential. As indicated by the test data in Table I, all of the 5,000,000-kva circuit breakers have been subjected to such factor-of-safety tests to be sure that the voltage-interrupting ability is adequate for any reasonable abnormal voltage condition to which it may be subjected in service. It should be recognized that some of this safety factor necessarily would be lost if, in the effort to save cost, proposals to reduce circuit breaker insulation levels should be pushed too far.

Heavier power-interrupting tests also have been made at normal line-to-ground voltage to the maximum power of the laboratory. By taking advantage of the maximum asymmetry in the short-circuit current, obtained by synchronous control of the laboratory closing switch, and by pretripping the test circuit breaker so that the contacts separate during the first cycle of fault current, single-phase power can be interrupted equal to slightly more

Table I. Factor of Safety High-Power Laboratory Interrupting Tests

Circuit Breaker Rating	Test No.	Single-Phase Voltage, Kv	Interrupting Current, Rms Amperes	Interrupting Time, Cycles	Equivalent 3-Phase Kva
138 kv, 5,000 mva, 3 cycles	1	160	160	2.4	77,000
	2	160	1,160	2.9	557,000
	3	160	3,500	2.8	1,680,000

than 1,500,000 kva, equivalent to a 3-phase fault approximating 4,800,000 kva. The oscillogram of Figure 7(A) shows such a test in which 12,200 amperes is interrupted at 132,000 volts to ground in a time of 2.4 cycles. Still higher powers up to twice this value of 9,600,000 kva are made available by shunting out one of the interrupting units in the test pole, and applying the full power at the laboratory at approximately one-half normal line-to-ground voltage across the half-pole unit. Such a test is shown in Figure 7(B) opening 24,500 amperes at 66,000 volts in 2.0 cycles. In verifying the interrupting ability of the 230-kv 10,000,000-kva circuit breaker for Grand Coulee Dam, even the test program just outlined fell a little bit short of the necessary power to demonstrate the rupturing capacity with a reasonable factor of safety.

Accordingly, further tests were made on a half-pole unit with the 44-kv transformer connection instead of 66 kv. By this means the oscillogram of Figure 7(C) was obtained, showing a short-circuit current of 36,200 amperes, which at 230 kv 3-phase would be a fault of 14,400,000 kva. Since the 60-cycle recovery voltage now was only two-thirds of the appropriate value for a single interrupting unit, it might be considered that this test was not valid in terms of both voltage and current involved in the interruption. However, the high rate of recovery voltage in the laboratory and amount of overswing at the first transient voltage peak, compared to the damped recovery voltage of a high-power fault circuit in the field, makes this test one of equal or even greater severity. In Figure 8 is replotted to a suitable time scale the recovery voltage transient from a symmetrical current interruption at 44 kv in the laboratory compared with the recovery transients from high-power 230-kv field tests at Grand Coulee Dam having both asymmetrical and symmetrical fault current. Not only is the rate-of-rise of recovery voltage highest on the laboratory test, but the amplitude of the first voltage peak is equal to or greater than both of the field test voltage transients. On this basis the 15-cycle reclosing test of Figure 9, opening a current a little more than the 25,000-ampere rating of the 10,000,000-kva circuit breaker, may be considered as imposing recovery voltage conditions on the interrupting unit at least as severe as would be encountered on a 230-kv system without pretripping and with only moderate current asymmetry.

Considering the wide range of voltage and current to which a circuit breaker is subjected during verification, it is remarkable how little variation there is in the interrupting time. The effectiveness of the multiflow principle of interruption, supplemented by a spring-driven oil piston to assist the interruption of low current, is indicated by the fact that currents from 0 to 100 per cent of the current interrupting capacity are all interrupted within the 3-cycle interrupting time. Interruption even at voltages approximating twice normal line-to-ground voltage only occasionally exceeds the rated time of three cycles. When considering piston-driven oil flow for the interruption of line-charging current with minimum arc restriking in comparison with self-generated oil flow alone or with parallel voltage-damping resistors, the ability to meet a flat 3-cycle interrupting time characteristic over the entire current range using the oil piston is a considerable advantage in its favor, as well as the interrupter-flushing action obtained during each operation.

The Leeds-Cushing paper[7] presented comparative results of heavy fault interruptions both in the Westinghouse High Power Laboratory and at Grand Coulee Dam on a 230-kv circuit breaker. These tests demonstrated that voltage conditions in the laboratory test imposed equal or greater severity as compared to the field tests. However, it is extremely valuable to have the opportunity of testing ultrahigh interrupting capacity circuit breakers directly on a power system to supplement and confirm results obtained in the laboratory. Further tests at Grand Coulee Dam are planned in the near future to carry single-phase fault interruptions to equivalent 3-phase fault values as high as 12,000,000 kva.

Standard and Rapid Reclosing Duty Cycles

The standard operating duty cycle for power circuit breakers has been based for a number of years upon the CO-15 second-

CO duty. The ASA Standard for Alternating-Current Power Circuit Breakers, paragraph 4-6.20.3b[13] says: "After a performance at or near its interrupting rating, it is not to be inferred that the breaker can meet its interrupting rating without inspecting and, if necessary, making repairs." The improvement in circuit interruption, particularly in the higher power 3-cycle circuit breakers described in this paper, has resulted in circuit breaker designs which are capable of performing their interrupting rating several times on the standard duty cycle without the necessity of inspection or maintenance. The rating factors given in Table I of NEMA Standard SG6-90[14] for repeated numbers of unit operations and for reclosing operations have been considered by operating people as unnecessarily drastic when applied to the most modern circuit breaker designs. Some liberalization of these factors is being made in a revision now in progress, but of necessity they must be standardized at values which can be met by a wide variety of circuit breakers. While some reduction in interrupting capacity is indicated by rapid reclosing tests on circuit breakers of the self-generated oil-flow type, the actual loss of interrupting ability on the second operation is not very great on 3-cycle high power circuit breakers which have been designed with an appreciable factor of safety in arc-rupturing capacity.

The data submitted in Table II is selected from the large number of interrupting tests made in the High Power Laboratory during the development and verification of the 3-cycle circuit breakers rated 5,000,000 kva at 138, 161, and 230 kv, and the 10,000,000-kva circuit breaker for 230 kv. Standard duty and rapid reclosing tests are included, with the fault power applied to a single-pole unit or only a half-pole as found necessary to demonstrate adequate interrupting ability.

Of particular interest is the 9-cycle reclosing test at 16,000 amperes, the oscillogram for which is shown in Figure 10. This represents voltage and current conditions applied to a single interrupting unit equivalent to a 3-phase fault of 6,650,000 kva at 230 kv.

Conclusion

From both theoretical considerations and the results of actual tests there does not seem to be any serious limitation on the maximum interrupting capacity of steel-tank oil circuit breakers equipped with heavy duty multiflow De-ion grid interrupters. Although 25,000-amperes interrupting capacity and 40,000-amperes momentary rating is close to the limitation of the butt-type contacts with silver-tungsten arcing tips, interrupters using finger-type contacts, with a slight increase in over-all interrupting time, can be made available if, in spite of more conventional practices limiting maximum fault power, still higher rupturing capacities seem justified.

By taking advantage of the inherently higher rate of rise of recovery voltage in undamped laboratory test circuits as compared to the overdamped transients under heavy fault conditions in the field, the test voltage in the laboratory may be lowered by as much as a third, thus expanding the available rupturing capacity by 50 per cent without serious loss in validity of the results.

High-speed reclosing, even at intervals as short as nine cycles, has been demonstrated satisfactorily, indicating that the circuit breaker need not be the limiting factor in establishing the shortest practical reclosing interval.

Discussion

Robert H. Nau (University of Illinois, Urbana, Ill.): The paper possesses two characteristics which are most desirable for a technical paper: it is well written and presents a new contribution to the technical field.

Two years ago Leeds and Cushing presented a technical paper before the Institute,[1] which described the advantages of a dead-tank circuit breaker. Too, it was shown that by correlating studies of oil-flow, orifice sizes, inertia-impeded levers, and of scavenging that a 7,500,000-kva 230-kv oil circuit breaker was designed. The laboratory and field tests indicated a sound basis for extending the controlled design to 10,000,000 kva.[2]

It is evident that the extension of the principles of controlled design has led to the notable contribution of an ultra-high-power high-speed supervoltage oil circuit breaker. In the new multiflow deion grid the relationship of the two contact breaks, the oil flow through the orifices, the superspeed of contact opening, and the supplementary action of the oil piston all function to quench the arc as expeditiously as possible without producing excessive gas pressures in the interrupters before the interrupting contacts have sufficiently parted to withstand a high-voltage recovery rate following the interruption of superpower short circuits. Also, the action positively assures interruption of low power-factor charging currents in the required 3-cycle time. The operation is evolved as expressed by the paraphrased adage, "It is easy to keep the multiflow orifices clean, if they are not permitted to become fouled."

It is, indeed, commendable that the 10,000,000-kva 230-multiorifice oil circuit breaker has an appreciable factor of safety above the required interrupting rating. The recorded test data and oscillograms indicate superior performance.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The resourcefulness and inventiveness of the authors and the enterprise of the company with which they are associated in

proceeding with and in bringing into fruition the development of high-voltage circuit breakers from 5,000,000- to 10,000,000-kva rupturing capacity cannot be too highly commended. Certainly those who are charged with the responsibility of planning and projecting the growth of modern power systems fully appreciate the importance of having circuit breaker development and extension in capability of rupturing duty of high-voltage circuit breakers march, not hand in hand with system growth, but actually in advance somewhat of system growth, if that growth is to be projected and take place on most economical lines.

Yet, recognizing in full the ingenuity of the designs developed, one cannot help speculating, upon looking at and analyzing the heart of the design as shown by Figure 4 of the paper, for example, whether ingenuity has not been carried too far. Anyone who has had some experience in the operation of equipment embodying that design cannot, it seems to me, help but wonder whether that much ought to be put together in a construction in which so much mechanism is hung in cantilever from the end of a bushing and made dependent for its successful operation by an assembly subject to as much mechanical misalignment, and therefore potential difficulty, as the operating head assembly shown in Figure 2 of the paper. What this gets down to, therefore, is the question of whether after all the same principle of action could not be made to function in a totally different assembly, possibly an oil-poor assembly where the basic or inherent mechanical weaknesses would be eliminated because they would be taken care of by positive design features.

H. P. St. Clair (American Gas and Electric Service Corporation, New York, N. Y.): I would like to request clarification of the oil dashpot feature described in the fourth paragraph of the section on Design Features of a Heavy-Duty Multiflow Interrupter. It is not clear to me either from the description in the text or the explanation of the drawing of Figure 4 of the paper, just how the dashpot incorporated into the other end of the grid-operating rod brings about an increase in the speed of opening the rocker-arm contact.

In testing and demonstrating the interrupting capability of the new circuit breaker in the laboratory, the authors have unquestionably made the best possible use of the available test capacity and these tests, including reduced voltage tests on a single interrupter or one-half of a complete pole unit, certainly go a long way toward proving that the circuit breaker will be able to meet its rating. In this connection it is comparatively easy to take the first step of using one-half voltage across the half-pole unit, relying upon the resistor voltage divider to insure equitable voltage distribution in normal operation. In taking a further reduction from 66,000 volts to 44,000 volts across the half-pole unit, however, the authors have made an interesting comparison of the greater severity of transient recovery voltage obtained in the laboratory with that obtained under field circuit conditions, and have used this comparison to justify the validity of regarding such a test as something at least roughly equivalent to a 3-phase 230-kv test at 14,400,000 kva. Even though I assume there was no serious intention of claiming a fully equivalent test of this magnitude, I believe it would be well to point out that the severe recovery voltage transient shown in Figure 8 of the paper was based upon a symmetrical short-circuit test at 20,700 amperes and 44,000 volts, whereas the 36,200-ampere test shown in Figure 7(C) of the paper was a totally offset wave. It is well known, of course, that when the current wave is completely offset, the current zero and voltage zero practically coincide and there is no recovery voltage transient at all. In other words, the use of the greater severity of laboratory circuits as an offset to the reduced voltage associated with higher current tests should be confined to more or less symmetrical short-circuit tests, of which the 20,700-ampere test shown in Figure 8(A) of the paper is an example.

This again points up the discrepancy between our American method of rating circuit breaker duties on the total rms value of current, including both d-c and a-c components, as compared with the European method of rating circuit breakers on the symmetrical current only. There is a growing conviction in this country, I believe, that the symmetrical basis for rating circuit breakers is a sounder method and should be adopted. At the same time, of course, the mechanical forces resulting from offset current waves must be taken into account both in design and testing.

Finally, it is gratifying to know that the authors find in their tests and development of this circuit breaker a further substantiation of the idea that some of us have been advancing for a number of years that derating factors for high-voltage high-capacity circuit breakers are entirely too severe. It is gratifying that these are being somewhat liberalized in present revisions, but it is hoped that it will not be long before the values called for in standards can go all the way in accepting the realities of modern circuit breaker designs.

A. M. deBellis (Consolidated Edison Company of New York, Inc., New York, N. Y.): This paper, describing the development of higher steps of interruption capacity in high-voltage outdoor oil circuit breakers, is most interesting to us. We now are installing a number of 5,000,000-kva circuit breakers on our 138-kv tie-feeder system. This is the largest interrupting capacity available at this voltage.

Even with this size of circuit breaker we find it will be necessary to install four sets of 138-kv reactors a few years hence, in order to maintain interrupting duties within the 5,000,000-kva rating. This naturally leads one to think of the possibilities of using higher interrupting capacities at this voltage.

The authors state that 25,000-ampere interrupting capacity is close to the limitation of butt-type contacts with silver-tungsten arcing tips. At 138 kv this limits interrupting capacity, with this type of contact, to about 6,000,000 kva. It would be interesting to know what may be involved to obtain 7,500,000 or 10,000,000 kva which, at 138 kv, would require an interrupting rating of about 44,000 amperes with a momentary capacity of 70,000 amperes.

It is gratifying to know that careful attention was given to the problem of interrupting line-charging currents with a minimum of arc restrikes. We operate an underground cable system only within New York City, at 138 kv. We are naturally interested in avoiding severe overvoltages on these circuits. Interruption of low currents without restrikes is not only desirable but practically essential on a system of this type.

I also want to compliment the authors on the attention given to the possibility of interrupting high current with a higher-than-normal recovery voltage across the contacts of the circuit breaker. The possibility of out-of-phase switching is always present.

G. D. Floyd (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): An AIEE Joint Subcommittee has been studying the matter of out-of-phase high-voltage switching. It is of interest to note that in the paper by Mr. Leeds and Mr. Friedrich, this matter was considered of sufficient importance to justify tests on a high-capacity high-voltage circuit breaker, and a reference to these tests and discussion of their significance is made in the section on Demonstration of High-Power Interrupting Capacity of their paper. I believe out-of-phase switching may become of more importance than it has been in the past because of more widespread interconnection of systems, and the desire to rapidly reclose tie lines or to reconnect generating sources that may be connected to a system by a single high-voltage line. It usually is not difficult to determine the amount of current the circuit breaker would be required to interrupt in attempting to re-establish the system tie. Therefore, if it can be demonstrated by a test on the circuit breaker before purchase that it can interrupt a specified fraction of its current interrupting capacity under voltage conditions equal to twice normal line-to-ground voltage, the purchaser would feel more confident that he had made a sound application.

W. M. Leeds: The authors appreciate very much the comments regarding the design and performance of the high-power oil circuit breakers described in this paper. Mr. Sporn expressed some concern regarding possible difficulty in maintaining alignment between relatively heavy stationary contact assemblies, mounted at the ends of slanted terminals, and a bridging contact assembly moved rapidly by a long lift rod. However, over 20 years of successful experience with this type of circuit breaker construction, including the 287-kv Hoover Dam circuit breakers with multiple grid assemblies twice as heavy as modern interrupters, has developed confidence in the mechanical adequacy of this steel tank circuit breaker design. Over 3,000 mechanical operations on the first 230-kv 10,000,000-kva circuit breaker as well as hundreds of short-circuit interrupting tests have been made without any difficulty due to contact alignment. Furthermore many high-power short circuits have been interrupted with one grid by-passed, resulting in unsymmetrical

Figure 1. 11,000,000-kva 13.3-cycle reclosing duty test

Figure 2. 11,200,000-kva 7.7-cycle reclosing duty test

Figure 3 (right). 230-kv 10,000,000-kva interrupter intermediate contact after nine tests 10,000,000 to 12,000,000 kva

transient forces, and yet no guiding difficulties were experienced.

Mr. St. Clair has asked for a clarification of the function of the oil dashpot feature on the contact operating rod of the interrupter assembly shown in the contact assembly of Figure 4 of the paper. The opening motion of contact, Figure 5 (B) of the paper, with a resilient connection but no dashpot action in the connection from the operating rod to the rocker contact is compared with Figure 5(C) having dashpot action. During the first inch of downward movement of both the lower contact and the side operating rod, the sum of the two contact gaps is three inches in Figure 5(C), rocker ratio 2:1, where the dashpot maintains the 3/8-inch compression of the contact spring during this time. In Figure 5(B) the spring is extended three-eighths of an inch almost immediately so that twice this dimension or three-quarters of an inch is subtracted from the pressure gap, the sum of the upper and lower gaps thus equalling only $2^1/_4$ inches after one inch of circuit breaker cross arm travel.

The criticism of the highly asymmetrical fault current tests shown in Figure 7 of the paper has been based on the assumed approximate coincidence of the normal frequency voltage zero with the final current zero. As a matter of fact, the cathode ray oscillogram for the test of Figure 7(C) shows nearly 70 per cent of the normal-frequency recovery voltage at current zero with a superimposed high-frequency recovery-voltage transient oscillation reaching a peak 25 per cent above the normal 60-cycle crest value. It is recognized, of course, that symmetrical current testing must be included in any circuit breaker verification, and it is for just this reason that lower 60-cycle transformer test voltages with overshooting recovery-voltage transients are employed to make available higher amplitude symmetrical short-circuit currents.

In the rapid reclosing test of Figure 9 of the paper, the second interruption required 3.3 cycles or slightly more than the rated interrupting time. However, it should be observed that this was not due to excessive arcing but included at least one-half cycle delay in the second trip operation on account of inadequate ampere turns in the trip coil. The oscillogram of Figure 1 of this discussion was taken after this condition was corrected, interruptions of 27,500 and 21,300 amperes being cleared in 2.2 and 2.6 cycles with a reclosing interval of 13.3 cycles. Figure 2 of the discussion shows a reclosing test with both interrupted currents above the 25,000-ampere rating and with the reclosing interval reduced to the remarkably short time of only 7.7 cycles. This emphasizes the fact that the circuit breaker need not be the limiting element in determining the minimum permissible reclosing time interval even for circuit breakers rated as high as 10,000,000 kva at 230 kv. As further evidence of the ability of these high-power circuit breakers to interrupt heavy faults repeatedly without maintenance, Figure 3 of this discussion shows one of the butt-type intermediate contacts after nine successive short-circuit interruptions of 25,000 to 30,000 amperes, all above the current interrupting capacity of the 10,000,000-kva circuit breaker.

Mr. deBellis believes that there soon may be a need for 138-kv circuit breakers rated 7,500,000 kva or even 10,000,000 kva. The interruption of currents as high as 44,000 amperes is considered to be a practical possibility, but the provision of 70,000-ampere momentary rating would undoubtedly require finger contacts, and a consequent increase of approximately one-quarter to one-half cycle in the time to part contacts as compared to the present butt-contact design. The circuit breaker interrupting time under these conditions would still be entirely satisfactory for most applications.

Both Mr. deBellis and Mr. Floyd have noted with approval the demonstration of interrupting ability up to double normal operating voltage, simulating out-of-step conditions on a tie-line circuit breaker. While there are no standard specifications in this regard, the company with which the authors are associated believes it to be desirable to check all new high-voltage circuit breaker designs up to approximately one-quarter of rated current interrupting capacity under these extreme conditions.

A Printing Telegraph Tape-to-Page Translator

A. E. FROST
ASSOCIATE AIEE

Synopsis: The tape-to-page translator is a device employed in a reperforator switching telegraph system to permit the delivery of telegrams, handled throughout the system as "tape" printer messages, to patrons' offices equipped with page teleprinters. This paper describes the means employed for inserting the additional characters and the necessary conversions in the transmission of a message to produce the traditional format of the copy received on a page teleprinter.

THE Western Union Telegraph Company has recently extended reperforator switching methods to the delivery of telegrams to tie-line patrons. Some of these customers have tape teleprinters in their offices, while others prefer page machines. Out of the fundamental differences in operating requirements of the two types of teleprinters arises the need for a translator.

Tape printers type characters on a narrow gummed tape which is affixed to a telegraph blank by the receiving operator. A hand-tape moistener and a thimble having a tape-cutting edge facilitate this operation. It is a simple matter for the operator to arrange lines of printing in a prescribed manner to produce the familiar telegram. One type of tape teleprinter operating position is shown in Figure 1.

Page printers type directly on a paper page of message blank width. The blank is usually in roll form and messages are separated by cutting the blank along a knife edge. Figure 2 shows a page teleprinter mounted in a console. This instrument can be used for both sending and receiving. It differs from the tape teleprinter in several respects, including the need for transmitting signals to effect carriage return and line feed functions.

By far the greater proportion of telegrams handled by the telegraph company are recorded on tape printers, and all business allowed to enter the reperforator switching system is in the form of tape printer copy. To permit messages flowing through the reperforator switching system to be switched automatically to page tie-lines, the differences between tape and page signaling requirements must be reconciled automatically. This is the purpose of the tape-to-page translator.

Figure 3 shows tape and page teleprinter character assignments. Only the differences between them are shown in the page columns. The abbreviations *UC* and *LC* refer to upper case and lower case respectively. The page printer has two of the 32 possible combinations of the 5-unit code assigned to carriage return and line feed. The tape printer has four characters assigned to these code combinations, which means that the tape printer has four character assignments that do not appear on the page printer. The omitted characters are: paragraph sign, equal sign, English pound sign, and the per cent sign. The equal sign is not required; neither, obviously, is the paragraph sign, since it is used only as an indication to the tape printer receiving operator that a new line should be started. The English pound and the per cent must be spelled out in page printer operation. The translator performs a conversion for the per cent sign but the pound sign occurs so infrequently that tape printer routine now requires it to be spelled.

Translator Requirements

The following is a summary of the functions to be performed by the tape-to-page translator:

1. Count a certain minimum number of characters for a line and insert a carriage return and line feed on the following word space.
2. Convert the equal sign into carriage return and line feed.
3. Convert the number sign (upper case equal sign) into upper case *H*.
4. Convert the apostrophe (upper case *N*) into upper case *S*.
5. Convert the per cent sign (upper case *M*) into letter shift, *PCT*, figure shift.
6. Convert the paragraph sign (upper case *S*) into carriage return, line feed, and five word spaces to give a proper paragraph indentation on the page printer copy.
7. Convert the comma (upper case period) into upper case *N*.
8. Convert the period into figure shift, *M*, letter shift.
9. On double period (end of message) transmit a carriage return and line feed; initiate a request for the time and date; and, upon completion of the transmission of the time and date, end the message by transmitting a carriage return and eight line feeds.

Translator Plan

Figure 4 shows a block diagram of the translator components and illustrates the plan chosen to effect translation. Tape teleprinter signals are received and perforated by the reperforator. The perforated tape passes through the tape transmitter, which sets up the code combinations punched in the tape, character by character, on five reading relays. The reading relays carry several sets of contacts for reading the character and an additional set of contacts from which the selection may be transferred to the storing relays should no translation be required. Associated with the storing relays is a sending distributor for transmitting the signals to a page teleprinter circuit.

Should a character requiring translation

Paper 50-13, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 15, 1948; made available for printing November 22, 1949.

A. E. Frost is with the Western Union Telegraph Company, New York, N. Y.

Figure 1 (left). Tape teleprinter operating position

Figure 2 (right). Page teleprinter console

be set up on the reading relays, a circuit is established to energize one of the translator relays. One translator relay is required for each of the nine functions and, when operated, it sets up the conditions required for the particular translation. Since most of the conversions require that more characters be transmitted than are received, it is necessary to establish a condition whereby a succession of conversion characters may be transferred, one at a time, to the storing relays. This is the purpose of the transfer relays. Operation of a translator relay immediately causes the operation of an appropriate transfer relay which carries contacts for the transfer of the first conversion character to the storing relays. Provision is made that this transfer shall take place from the transfer relays and not from the reading relays; that is, the first conversion character is transferred to the storing relays in place of the character requiring translation. Then a second transfer relay is operated and the first one released to effect the transfer of the second character to the storing relays. This process is repeated as many times as is required. The operation of the last transfer relay establishes circuits for the restoration of normal transmission.

It is fundamental that transmission to the translator must be stopped during the transmission of additional conversion characters. The perforated tape furnishes the necessary loose coupling between the originating transmission and the translator. The tape transmitter is stopped and started again by the translator as required.

The translator is provided with two items not shown in this diagram. One is a counter to count the number of characters in each line of page copy to indicate that a carriage return and line feed should be inserted upon the reception of the following word space: the other is a rotary switch used to effect the transfer of the conversion characters for the paragraph sign and also the carriage return and eight line feeds at the end of a message.

Transfer and Storing Relay Circuits

All of the events required by translation are timed from local rings on the sending distributor shown in Figure 5. The distributor brushes are continuously rotating.

Local segments are shown in proper relation to the sending segments. Stepping of the transmitter takes place during the transmission of the start impulse. An auto-stop relay, differentially wound, is included in the circuit to stop the transmitter and hold its contacts to spacing when the auto-stop circuit is opened due to tight tape or because additional characters need be inserted for a translation. The count pulse steps the counter, resets it and releases certain transfer relays. The following segment is used to operate and release relays. The read pulse seeks a path through contacts of the reading relays to operate translator relays. The switch step segment steps the rotary switch for the conversion of the paragraph sign and for the message-ending characters. Timing of the transfer of a character to storing relays is done by the transfer segments.

Because of the number of conversions required in translation, the transfer of the desired selection to the storing relays was kept as simple as possible. The storing relays must be capable of responding to any one of 13 transfer relays and to 16 positions of the rotary switch in addition to the reading relays. The circuit is arranged so that a closed circuit to battery from any of the transfer points will prepare for the transfer of a marking signal to a storing relay and that an open circuit at all of the transfer points will effect the transfer of a spacing signal. This allows all of the transfer points to be paralleled. It is merely necessary, at the time of transfer, to insure that only the desired circuits are closed.

The operating circuit of the fifth storing relay is shown. When any one of the fifth pulse transfer points is closed, the relay is

energized as the local brushes pass over the fifth transfer segment. The relay locks up to negative battery, and during the following revolution of the distributor a marking fifth pulse signal is transmitted to line. Should the next fifth pulse signal be spacing, all of the transfer points would be open as the brushes pass over the transfer segment in this revolution. Positive battery, through the transfer segment, is applied to the locking circuit in opposition to the negative locking battery, and the relay releases. On the following revolution of the distributor a spacing signal is transmitted to line. The location of the transfer segments is such that a storing relay will not be disturbed during transmission from its contacts.

Since the distributor brushes are continuously rotating, it is desirable to short-circuit the distributor when no intelligence is being transmitted. This, and to prevent the counter from stepping on blank characters, are two of the reasons for providing the cut-off relay. The cut-off pulse occurs during the transmission of the rest pulse, an essential requirement to avoid mutilating a character. Blank reading contacts determine the position of the cut-off relay.

Two of the more simple conversions have been chosen to describe in some detail. They are representative of the translator functions.

Equal Sign Conversion

Figure 6 shows the circuits involved in converting the equal sign to carriage return and line feed. When an equal sign is stepped into the transmitter, a marking second pulse is set up on the reading relays.

This occurs at the beginning of the transmission of the previous character to the page tie-line. The second pulse is read through contacts of the reading relays, operating the equal sign relay, which locks.

The carriage return transfer relay is immediately operated from contacts of the equal sign relay through contacts of the upper case relay. When the transfer takes place, the fourth storing relay is operated from contacts on the carriage return transfer relay. It will be noted that the second pulse set up on the reading relays is open at contacts of the equal sign relay. On the following revolution of the distributor, a fourth pulse for carriage return will be transmitted to the page tie-line. While the carriage return character is being transmitted, the auto-stop relay is operated by the transmitter step pulse because the auto-stop circuit is open at the equal sign relay. The transmitter magnet is energized, holding the transmitter contacts to spacing. The operate pulse operates the line feed relay which locks and releases the carriage return relay. When the local brushes pass over the transfer segments the second storing relay is operated and the fourth is released. On the next revolution of the distributor a second pulse for line feed is transmitted. During this revolution it is desired to reset the counter and restore

Figure 5. Transfer auto-stop, and cut-off circuits

Figure 6 (above). Conversion of equal sign to carriage return and line feed

Figure 7 (below). Conversion of paragraph sign to carriage return, line feed, and five space characters

Figure 8 (right). Tape-to-page translator rack for three translators

the circuits to normal. Operation of the line feed relay closed the auto-stop circuit which was opened by the equal sign relay. The transmitter pulse now releases the auto-stop relay and the transmitter steps the tape to the following character and sets it up on the reading relays. The count pulse resets the counter and also releases the line feed transfer relay. The operate pulse releases the equal sign relay, thus completing the conversion and the restoration of the circuits to normal.

For the natural end-of-line conversion, when the counter contacts close and the following word space is read, the same carriage return and line feed transfer relays are used.

Whenever a second pulse is read, whether upper or lower case, the equal sign relay responds. In the lower case the conversion of equal sign to carriage return and line feed takes place as described. In the upper case, however, the upper case relay is operated and, instead of operating the carriage return relay, the circuit is directed to another transfer relay for the conversion of the number sign.

Paragraph Sign Conversion

Figure 7 covers the conversion of the paragraph sign into carriage return, line feed, and five word spaces. The paragraph sign is upper case *S*. Therefore an upper case signal must have been received and read and the upper case relay operated and locked up. This completes the circuit for the operation of the paragraph relay when a 1, 3, marking combination is read. When the paragraph relay is operated the 1 and 3 transfer circuits from the reading relays are opened. The rotary switch step circuit is closed; the switch is stepped from the switch step segment, and through level 2 a fourth pulse for carriage return is transferred to storing relay number 4 in the same revolution in which the paragraph sign is read. On the following revolution the transmitter is auto-stopped; the switch steps again and then a second pulse for line feed is transferred to storing relay number 2. On each of the following five revolutions a third pulse for "space" is transferred to storing relay number 3. On the next to the last of these steps, a circuit is established through level 3 of the switch to prepare for the resumption of normal transmission. The restoring relay is operated by the operate pulse on the next revolution. This closes the auto-stop circuit so that on the following revolution the auto-stop relay re'eases and the transmitter stops. The count pulse releases the restoring relay and resets the counter. The operate pulse releases the paragraph relay, which completes the translation.

The application of the rotary switch for this translation is simplified because the conversion characters have a single marking impulse code. A fourth level on the same rotary switch is used for the end-of-message translation.

Figure 8 shows the front view of the tape-to-page translator rack. Each rack accommodates three translators. Each of the three shelves shown carries a reperforator, a transmitter, and a monitor unit.

The monitor unit houses the counter for indicating the end of line, signal lamps, and a monitor jack. The relay banks, distributors, and rotary switches are mounted on the rear of the rack.

Application

In practice a tie-line sending installation may involve as many as 20 or 25 tie-line transmitters, any one of which can transmit to any one of a maximum of 600 tie-lines served by a central office. The division of the tie-line traffic load between tape teleprinters and page teleprinters varies in different localities. The average is about half and half. Therefore, only about one-half as many tape-to-page translators are required as there are tie-line transmitters. The translators are installed on a concentrator basis in such a manner that when a transmitter has a message for a page tie-line it will obtain the connection through an idle translator. The request for a translator is wholly automatic and the tie-line operator need not know to which type of teleprinter the message is being transmitted. The operator places the message, in the form of printer perforated tape, in the transmitter. After noting the address, she cords the transmitter into the tie-line jack corresponding to the address. Should the patron have a page teleprinter, the circuits established will request a translator, and when the connection is obtained the transmitter will start. This transmitter at the sending position sends to the reperforator on the translator rack. The output of the translator transmits directly to the page tie-line.

The first application of the tape-to-page translator is with the new tie-line sending installations, beginning with those in the Boston office of the Western Union Telegraph Company. It is found to be very effective in improving the speed of service and efficiency in the delivery of telegrams to patrons' offices equipped with page teleprinters.

No Discussion

Lightning Arresters as a Criterion for Insulation Levels

HAROLD L. RORDEN
MEMBER AIEE

THE cost of high-voltage transmission equipment, particularly transformers and circuit breakers, is so heavily influenced by insulation that insulation levels should be chosen which are as low as are safely possible. Recent estimating data received from large manufacturers indicate that, within practical limits, the cost of average large power transformers, when purchased at recognized levels, is directly proportional to the basic impulse insulation level. The ratio of cost to the basic insulation level is greater than unity for smaller transformers, and less than unity for the larger ones. In a recent purchase of 230-kv oil circuit breakers, the ratio of reduction in cost to corresponding basic insulation level was greater than 1.5 to 1 and involved levels not recognized as standard.

Present generation and transmission facilities are far behind load requirements in the Northwest. On the basis of volume of new equipment contracted for by the Bonneville Power Administration within the past year for transmission voltages of 115 kv and above, a difference of 5 per cent in the basic insulation level could involve a difference in cost of a $250,000 annually. Somewhat greater reductions in basic insulation level than this seem feasible.

Basic Insulation Levels

Analyses and practice show that the presently-recognized basic impulse insulation levels are too conservative for the higher voltage systems, particularly since these systems are predominantly of the grounded-neutral type. This question is being considered by AIEE Standards Coordinating Committee Number 8. These basic insulation levels are substantially in linear relation to their respective operating voltages, and while they are not adopted standards, they have been accepted by the industry as defining the full-rated insulation level for the respective voltage classes regardless of the degree of grounding of the equipment. Many departures have been made from recommended levels, usually in terms of full steps because these steps only have been recognized as standard practice.

It would seem that available basic insulation levels should be such that the user can select a level that he decides is practical and economical for his system. If wide gaps exist between available insulation levels, the user may find it to his economic advantage to depart from standards; whereupon the standards cease to serve their intended purpose.

System Transients

Of the four types of transient voltages that commonly occur on modern high-voltage systems, lightning and switching surges are the most severe. They are the only ones which approach being dangerous to insulation, and of these, switching surges are not usually serious. By test, as well as from operating records, switching surges on the 230-kv Bonneville system only occasionally exceed twice normal voltage and are not known to have exceeded three times normal. These test potentials occurred on the line side of the circuit breaker during de-energizing an unloaded circuit, and were considerably lower on the bus.

The two dynamic transients produced by load rejection with accompanying overspeed, and unbalance due to faults can reach more or less the same overvoltage which is not high enough to endanger insulation. Voltages resulting from load rejection and subsequent instability have reached 40 per cent above normal on the Bonneville system. Calculations with the circuit impedances of the system (X_0/X_1 and R_0/X_1) indicate that under the worst fault conditions voltages can reach a maximum of 30 per cent above normal on the 115-kv system and 7 per cent above normal at any present 230-kv station containing transformation.

About Lightning Arresters

It seems logical to base impulse insulation levels on the levels to which a protective device such as lightning arresters can limit lightning surges. The minimum insulation level to which station equipment can be designed, using lightning arrester protection, includes:

1. A margin between the voltage rating of the system (line to ground for grounded-neutral equipment) and the voltage rating of the lightning arrester.

2. The voltage difference between the lightning arrester rating (converted to crest kilovolts) and its surge discharge voltage (protective level).

3. A margin between the protective level of the lightning arrester and the insulation level of the equipment.

With reference to the first item, if the system designer selects a lightning arrester rating below the dynamic transient voltage levels of his system, he is taking a risk, not on transmission equipment failure, but on lightning arrester failure. However, other factors might reduce the risk to the point where such a selection could be considered good practice. The

Paper 50-14, recommended by the AIEE Protective Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 20, 1949; made available for printing November 22, 1949.

HAROLD L. RORDEN is Protection Engineer with the Bonneville Power Administration, Portland, Oreg.

Credit is due to the personnel of the Ohio Brass Company, particularly P. M. Ross and V. L. Crabb, for contriving the test line which made the lightning arrester tests possible, and for the efficiency and precision with which the tests were conducted; and to Ralph S. Gens of the Bonneville Power Administration for assembling and analyzing the data.

Figure 1. One-mile test line—the Ohio Brass Company High Voltage Laboratory

lightning arrester requires an initial transient voltage considerably in excess of any dynamic transient likely to be sustained in order to initiate lightning arrester discharge. This initial breakdown voltage is above most switching surges at the bus, so that it commonly requires lightning to set off the lightning arresters on unfaulted conductors at the instant the excessive dynamic voltage is impressed on the lightning arrester; otherwise no failure occurs. This may be possible, but the lightning voltage waves are usually on faulted conductors, and the unfaulted ones do not reach potentials that start lightning arrester discharge. In load rejection, surges caused by lightning have terminated before system swing and overspeed result in voltages that could destroy lightning arresters. No lightning arrester failure has occurred from load rejection on the Bonneville system. Two such cases are known by records to have resulted in dynamic voltages above the lightning arrester ratings on the 230-kv system.

Figure 2. Test line with lightning arresters 200 feet from station

If the system designer wants full assurance that his lightning arresters cannot fail from dynamic overvoltages, he must weigh the cost. A 3-pole 230-kv 80-per cent station-type lightning arrester, including labor of installation and fence enclosure, costs about $9,000 according to recent figures. Replacement of a single pole costs about $2,500. A reduction in basic insulation level of 5 per cent for a large 230-kv transformer bank and circuit breaker could save the user $30,000 to $50,000. A 42 per cent margin of lightning arrester rating over normal voltage is generally recommended for grounded-neutral systems. Normal line-to-ground voltage is 59 per cent of the line-to-line value, and recommended lightning arrester levels are 84 per cent (80 per cent with 5 per cent tolerance) for grounded-neutral service. This margin seems more than is necessary to protect lightning arresters from dynamic transients for many applications. What degree of risk might the user take, balancing the first cost versus the possibility of a lightning arrester (not transformer or circuit breaker) failure, involving an interruption to service and replacement of the lightning arrester (probably one or two poles); or is he taking much chance? If he has been using full-rated basic insulation level and can satisfy himself that it can be reduced from 10 to 25 per cent without taking much risk, it should be worthy of consideration.

Figure 3. 97-kv station-type lightning arrester with discharge counter and 90-kv line-type lightning arrester mounted for test

Figure 4. Surge testing lightning arresters, Ohio Brass Company Laboratory, Barberton, Ohio

For the second item the difference between the rating and the protective level of lightning arresters must be charged to defense of lightning arresters as the criterion for establishing insulation levels. Other forms of protection such as gaps may permit lower levels, but since they involve interruptions to service, they cannot usually be tolerated in large high-voltage stations. The combination of gap protection with high-speed reclosing circuit breakers offers possibilities for low basic insulation levels and an acceptable standard of service, including possible elimination of ground wires for other than station protection. The third item involves tolerances in lightning arrester performance and a factor of insurance against unknowns colloquially termed the "ignorance factor."

About Lightning Waves

The first line of defense for station equipment against lightning is the ground wire with low tower and station footing impedances, and if the combination is adequate, steep-fronted direct strokes are eliminated from the station. If ground wires are used for station protection only, the most severe anticipated surges to reach station equipment are traveling waves from hits to the conductor beyond the ground-wire area. If the entire system is protected with ground wires, only occasionally do voltages occur of sufficient magnitude to flash over insulation and invoke the use of additional protection.

Lightning protection of 230-kv stations on the Bonneville system containing transformers consists of overhead ground wires extending approximately one mile over all lines from the stations, station-type lightning arresters for grounded-neutral service, and low-resistance ground mats. The 115-kv stations are protected with one-half mile of ground wire over all lines, and full-rated lightning arresters at those stations where the transformers are delta connected. Transmission lines beyond the ground-wire area adjacent to stations are not protected from direct strokes.

As far as is known, all strokes to conductors result in flashovers at the nearest tower or towers (usually the nearest tower in both directions from the hit). The resulting wave that travels toward the station is therefore steep fronted and then chopped to some lower level determined by the impedances at the flashed over towers. Since it has a mile or more to travel, the steep-front, short-duration part of the wave is attenuated and becomes unimportant, so that a wave which may be of long duration but cannot be of a magnitude above critical insulator flashover enters the station. On wood-pole lines, flashover to ground also occurs at the structures nearest the point hit, and a wave of high magnitude travels down the line. This wave is chopped as it enters the protective ground-wire area to the level of the insulation at that point unless the potential is already below critical flashover. Flashovers also may have occurred at guyed structures or others with grounds brought near the pole top some distance from the hit.[1]

Traveling waves that enter the station are therefore limited in magnitude. The free wave that approaches the station may be considerably distorted in form, but any instantaneous value thereof obeys the relation $e=iZ$, where $Z=\sqrt{L/C}$ is the surge impedance of the line. With usual 230-kv insulation levels the critical flashover is 1,600 kv or less, the surge impedance is about 450 ohms, and so the current of approaching waves within the ground-wire area cannot exceed about 3,500 amperes and is less on lines with lower insulation levels. Since the ratio of voltage to current of the free wave is a constant, the voltage and current waves entering the station are of the same shape and cannot be displaced in time relation to each other.

Where surges of this nature and magnitude occur, they must be relieved by supplemental protective devices such as lightning arresters, since building equipment to withstand these voltages is impractical and uneconomical. In past practice, where a high margin was maintained between lightning arrester protection and basic insulation levels, standard 10/20 lightning arrester tests have been adequate. With reduced basic insulation levels, lightning arresters should be tested under conditions more nearly approximating service, particularly with respect to rates of rise of currents. This question is under consideration by the AIEE Protective Devices Committee. It would seem that appropriately lightning arresters should demonstrate their ability to pass current without restricting the initial current with respect to time, since the ability of the lightning arrester to pass current determines its initial protective level. Also, since it is the function of lightning arresters to protect station equipment, it would seem that they should demonstrate their ability to protect transformers under the same test conditions applied to transformers.

Tests of Lightning Arresters

The Bonneville 230-kv system is designed on the premise that the function of lightning arresters is to maintain an adequate protective level for traveling waves due to hits to conductors a mile or more away from stations. Because of the importance of maintaining adequate protective levels for reduced insulation of station equipment, a series of lightning arrester tests was conducted under conditions considered representative of the service to which lightning arresters are subjected on the system.

Facilities of the Ohio Brass Company were leased for these tests, and a mile of test line using number 4/0 aluminum-cable steel-reinforced conductor was constructed in the vicinity of the laboratory. The location of this line is shown in Figure 1, and the type of construction is illustrated in Figure 2. Both ends of the line terminated in the test area, so that records could be readily obtained at both ends. Average height of the line was 30 feet, and it was insulated with 15 $5^3/_4$-inch

Figure 5. Voltage waves at the sending and station ends of the 1-mile test line

Figure 6 (above). Waves of Figure 5, on condensed time scale

Figure 7 (right). Performance of station-type lightning arrester to traveling wave

suspension units. A station-type lightning arrester with surge counter, and a line-type lightning arrester are shown assembled for test in Figure 3. The surge generator and test platform are shown in Figure 4.

The surge generator was connected to have capacitance of 0.0716 microfarad, and to have a nominal voltage of 1,050 kv. Potentials at the sending end of the line reached about 800 kv which was considered sufficient to test lightning arresters for 115-kv grounded-neutral service. Connecting the generator to obtain sufficient potential to test 230-kv lightning arresters appeared impractical due to the short wave length of the resulting surge sent over the line. The surge impedance of the test line was measured to be about 445 ohms, the inherent inductance of the surge generator 40 microhenries, and its inherent resistance less than 2 ohms. Negative polarity was used throughout the tests except for a few at positive polarity for comparative purposes. Voltage records were obtained with the usual type resistance divider and currents by means of a twisted-pair shunt.

Tests were conducted on four station-type lightning arresters, each stacked to 97-kv rating and on three line-type lightning arresters, each consisting of three 30-kv units stacked so as to obtain a nominal voltage rating of 90 kv. This line-type arrester is beyond rated limits, but it was desired to determine whether its use on 115-kv systems appears feasible for traveling waves. The station-type lightning arresters consisted of two stacks each of the types made by two different manufacturers, denoted by *A* and *B*. One stack of each manufacturer, denoted by subscript 1, was taken from Bonneville stock, but which had never been in service. The other stack of each of the manufacturers, subscript 2, was removed from service for the tests. Line-type lightning arresters were all purchased for the tests and consisted of one each of three different manufacturers.

Except for voltage and current levels given in Table I, the oscillograms are representative of all similar lightning arresters tested, unless otherwise stated. Oscillograms showing a plurality of traces of similar characteristics, such as volt-time, were obtained by successive tests, and deflections on the records are directly comparable. Figure 5 illustrates the volt-time surge waves used in the lightning arrester tests. The wave at the sending end is equivalent to 0.4 by 22 microseconds and was impressed on the line directly from the surge generator without any extraneous impedances in the circuit. At the far end, hereinafter denoted as the station end of the line, the voltage has doubled due to reflection from an open end.

One-half of the recorded crest potential equals 85 per cent of the sending-end voltage, the difference accounting for the losses in the wave traveling one mile. At the station end the front has attenuated to about $2^1/_4$ microseconds. It is believed that this station-end wave is fully equal in magnitude, wave front, and initial energy to the more severe waves that reach stations protected with a mile of ground wire and entering over a line having the insulation level used in these tests. In fact, during preliminary tests the bus insulator stack supporting the test line at the station end flashed over. This insulation level is 40 per cent higher than is used on the Bonneville 230-kv system.

In Figure 5 the time interval between the wave fronts at the sending end and the station end is an accurate measure of the length of the test line, the oscillograph being synchronized to start recording from initiation of the surge generator for both records. In Figure 6 these same waves on a condensed scale show the wave shape after reflections occur. The steep but short overvoltage "kick" at the crest of the sending-end wave does not appear at the station end.

Station Lightning Arrester Tests

Figure 7(A) compares the lightning arrester voltage at the station end with the lightning arrester current, and illustrates the ability of the lightning arrester to pass current commensurate with the traveling wave voltage impressed upon it. The voltage wave reaches its crest after series gap breakdown in a fraction of a microsecond. The lightning arrester passes about 70 per cent of its maximum current almost instantaneously after gap flashover as is shown by the steep-fronted current wave, and in about 2 microseconds it passes maximum current. The initial voltage rises above the level of gap flashover, but falls to a flatter slope as the lightning arrester reaches its maximum current. Since the volt-time characteristic of major insulation also curves upward at the short time intervals, this initial rise is probably not serious. It is believed that the lightning arrester currents shown in this test are comparable to modern service conditions. The equivalent of this type of test was suggested some time ago.[2]

Figure 7(B) illustrates the same test as Figure 7(A) on a condensed-time scale.

Figure 13. Performance of station-type lightning arrester with high current, no test line

Figure 15. Performance of line-type lightning arrester at the station end

After return of the first reflected wave, the lightning arrester voltage response to the current wave is commensurate with published data for the 10/20 waves.

The first four columns of Table I list the voltages and currents of all station-type lightning arresters tested as in Figure 7. The test voltage levels are compared with standard 10/20 waves in Figure 8(A). Where repeat tests were made, the highest only is shown in the table and in Figure 8(A), since any lower values could not be depended upon as protective levels. Tolerances ranged from ±1 per cent to ±7.5 per cent from average for the four lightning arresters. The lowest level in Table I is about 4 per cent above industry average for the same current with the 10/20 wave, and the highest is about 15 per cent above that level. From these limited tests it would appear that modern lightning arresters can maintain a crest protective level for steep-fronted surges that is about 15 per cent above those of the 10/20 wave test.[4] There appears to be no uniformity or general trend in the performance of new versus used lightning arresters of the types tested.

Figure 9(A) compares the voltage at the station end (transformer location) with and without a lightning arrester. Without the lightning arrester the potential reached over twice the level of the full-rated basic insulation level for 115-kv equipment (basic insulation level–550 kv). The lightning arrester limited the surge crest to about 350 kv, reducing the potential to less than 30 per cent and providing a protective margin which appears somewhat greater than is necessary. Although the surge wave without the lightning arrester reaches its crest in more than two microseconds, the crest maintained by the lightning arrester resulted from a steep fronted wave and reached its maximum voltage level in about one microsecond. It would seem that this 80 per cent lightning arrester could adequately protect an 80 per cent basic insulation level (440 kv) even if the insulation curve were flat, and if the lightning arrester rating can be reduced proportionately.

Figure 9(B) shows the voltage when the lightning arrester at the station end was paralleled with a capacitance of 3,300 micromicrofarads (approximating an average small substation with one transformer bank). For Figure 9(C) the arrester was placed 200 feet from the station end, but the 3,300 micromicrofarads remained at the end of the line. Comparison of the several records of Figure 9 led to the conclusion that station capacitance and the location of the arrester play important parts in station protection. The addition of capacitance in the test circuit results in a resistance-inductance-capacitance-loop which, because the effective resistance of the combination of the lightning arrester and the line surge impedance is below critical damping, becomes oscillatory. Although the crest level obtained in Figure 9(C) at the capacitor would still protect 115-kv transformers with full-rated basic insulation level it probably would not afford protection at levels reduced by any appreciable degree. The nature of the circuit, as revealed by Figure 9(C), leads to the conclusion that the size of stations, location of the equipment contained therein, and the number of lines terminating at the bus

Figure 14. Initial breakdown and protective level of lightning arresters at the station end

Figure 16. Voltage waves at the station end with and without line-type lightning arrester at points indicated

Figure 17. Performance of line-type lightning arrester to high current surges

Figure 18. Performance of line-type lightning arrester to steep front, high current surge

are all of major importance in the protective level than can be provided by lightning arresters.

Figure 10 compares the voltages at the station end and at the lightning arrester with the lightning arrester 200 feet from the station end, for lumped capacitance versus distributed capacitance, and for the arrester connected with a "T" tap versus "V" or hairpin tie. For these tests the total station capacitance of 13,200 micromicrofarads approximates that of a large substation. Comparison of Figures 10(A) and 10(B) shows that the effect of assuming lumped versus distributed capacitance within the station has an appreciable effect upon the protective levels maintained by an arrester some distance from the protected equipment. The capacitances of Figure 10(B) consist of four 3,300-micromicrofarad units spaced at 50-foot intervals. A comparison of Figure 10(B) with 10(C) illustrates that for a station of this size there is little advantage by use of the hairpin tie.

Figures 11 and 12 illustrate a comparison for the same applied surge to different voltage ratings of a lightning arrester. The initial crest voltages are in linear relation to each other but are not proportional to the voltage of one unit. After current crest the voltage levels are linear and proportional. Figure 12 includes data for both types of lightning arresters.

Higher current tests were conducted with the lightning arresters at the surge generator and without the test line. Figure 13(A) shows the voltage and current levels while Figure 13(B) illustrates the volt-ampere characteristic with the parameter microseconds marked on the trace. At these currents of over 12,000 amperes, all lightning arresters reached their lowest resistance in $2^1/_2$ to 3 microseconds. The initial current shown by the steep rate of rise appears to be of the same order as for the lower current tests of Figure 7. The fall in voltage that occurs before current has reached its crest may be due in part to the limit of energy of the surge generator.

The initial flashover and voltage protective level for the station-type lightning arresters at the station end are shown in Figure 14(A) on an enlarged scale. The initial steep wave front, the point of gap flashover, and the voltage protective level are well defined.

Line-Type Lightning Arresters

Similar tests to those conducted on station-type lightning arresters were conducted on three line types with surprisingly similar results. Figure 14(B) records a 90-kv line type test at the station end which is directly comparable in magnitude on the oscillogram to the same manufacturer's 97-kv station-type lightning arrester of Figure 14(A). This and other tests of the same lightning arrester show the crest and voltage protective level of the line type to be slightly the lower for this wave. Comparison of another line type and corresponding station-type lightning arrester showed the line type to have a level 9 to 16 per cent higher.

Comparison of Figure 15 with Figure 7(A) shows the similarity between the line-type and the station-type lightning arresters for these tests. The protective levels of the 90-kv line types are given in columns 7 to 9 of Table I and are compared with extrapolated 10/20 levels in Figure 8(B). Figures 8(A) and 8(B) and columns 5 and 6 of Table I compare line and station-type protective levels.

The records of Figure 16 appear to indicate adequate protection with the lightning arrester 200 feet from the station end and show some advantage in reducing the oscillations by the hairpin tie.[4,5] These tests, unlike those of Figures 9 and 10, were conducted without added capacitance, and so they are not considered comparable to usual conditions in service.

Figure 17 shows the performance of a line-type lightning arrester without the test line. This 90-kv line-type lightning arrester is rated 7 per cent below the station-type lightning arresters of Figure 13(A) and has an equal protective level for this test.

It may be implied that for equal voltage ratings and surges comparable to this test, the protective level of the line type is less than 10 per cent above the station lightning arrester. The cost of line-type lightning arresters is less than half that of station types.

Comparison of voltage and current with the corresponding volt-ampere characteristic is shown in Figure 18 for a line-type lightning arrester at the sending end of the line.

Summary

Considerable savings are possible by selecting insulation levels for high-voltage

equipment that are as low as are feasible. This involves study of the cost and standard of service versus the degree of risk that can be assumed for the possibility of failure of the protective devices.

It seems desirable to use lightning arresters as a basis for determining basic impulse insulation levels for which lightning arrester characteristics must be known for conditions in service. The following conclusions are drawn from lightning arrester tests conducted under conditions believed comparable to those of the Bonneville Power Administration system:

1. The surges to which lightning arresters may be subjected in service have steeper fronts than the 10/20 wave.

2. On the basis of limited tests the protective level of station lightning arresters for traveling waves entering stations protected with a mile of ground wire should be about 15 per cent above industry standard 10/20 wave levels.

3. For tests with currents unrestrained with respect to time, after the lightning arrester current reaches maximum the protective level of a number of lightning arrester units stacked is proportional to the number of units in the stack.

4. An 80 per cent lightning arrester can protect an 80 per cent basic insulation level in terms of presently recognized ratings. If the lightning arrester level can be reduced further, the basic insulation level can be reduced in proportion.

5. Characteristics of line-type lightning arresters are similar to corresponding station types. For traveling waves of the nature used in the tests, line-type lightning arresters can provide protection for grounded station equipment at least up to 115 kv at a level only slightly above that of station-type lightning arresters.

6. Best protection for transformers is obtained by placing lightning arresters close to their terminals.

Discussion

E. C. Starr (Oregon State College, Corvallis, Oreg.): The results of the tests reported in this paper are particularly gratifying to transmission engineers, in that they demonstrate the ability of modern lightning arresters to provide excellent protection against traveling-wave surges, even though they may be of extremely steep-front character, including the steep-front currents that may actually be encountered in practice. It is indicated that on the basis of the standard 10x20-microsecond current-wave test the momentary initial over-voltage across the lightning arrester, when discharging the same currents with a 2- to 3-microsecond front, may be of the order of 15 to 20 per cent. It is shown further, however that the duration of this momentary overvoltage is very brief, lying within the short-time high-strength region of transformer insulation. If the relative disruptive value of these voltage waves and the standard $1^1/_2$x40-microsecond wave when applied to transformer insulation were determined and presented, a further important step in clarifying the protection problem would be made.

Tests made during the program described by Mr. Rorden indicate the influence of length of circuit between transformer and lightning arrester, and of the surge capacitance of the transformer and its bushing. A traveling wave of sufficient magnitude to discharge the lightning arrester sets up a relatively simple resistance-inductance-capacitance oscillation between the lightning arrester and transformer that may result in higher crest voltages at the transformer than at the lightning arrester. The highest voltages for a given length of lead between lightning arrester and transformer were obtained with relatively low values of capacitance, while high values of capacitance both decrease the steepness of front and the magnitude of voltage impressed upon the transformer.

Figure 1 of this discussion presents a number of curves obtained from these data. The impinging traveling wave of current and voltage was much in excess of the lightning-arrester gap voltage and had a front of approximately 2.5 microseconds. The curves of voltage at the transformer as a function of time are actually envelopes of the crest values obtained when the equivalent transformer capacitance was varied from zero to a value so high that the initial wave front was slowed down considerably and the amplitude reduced as shown. The bottom curve indicates that for lightning arresters located immediately adjacent to transformers, the margin between transformer-insulation withstand voltage and lightning-arrester block voltage at the 8-microsecond point is actually increased for the shorter-time crests. For a 50-foot separation between lightning arrester and transformer, the 30-per cent margin at eight microseconds is reduced to approximately 16 per cent at 1.5 microseconds, and a 20-per cent margin at eight microseconds is reduced to approximately 6 per cent at 1.5 microseconds. For a 200-foot separation between lightning arrester and transformer certain values of transformer capacitance reduce the indicated margin from 30 per cent at 8 microseconds to slightly less than zero in the 2- to 4-microsecond region. While the data on transformer withstand strength and momentary overvoltage produced by lightning-arrester separation distance and transformer capacitance are not directly comparable, because of different wave shapes involved in the transformer withstand test, the results are indicative of the order of the margins to be obtained. It seems apparent that for separation distances of 50 feet or less, a margin of 25 per cent between transformer-insulation withstand value and the lightning arrester 10x20-microsecond standard block voltage, with due allowances for lightning arrester positive tolerances, should be adequate. Based upon these conclusions the following formula is suggested for determining the required insulation level of equipment to be protected by a given station-type lightning arrester located in relatively close proximity to the protected equipment in well-shielded stations:

$$\text{BIL} = (E_{avg} \text{ at } 5{,}000 \text{ amperes}) \times 1.067 \times 1.25 \text{ kv}$$

The first term is the industry average station-type lightning arrester 10x20-microsecond current-wave block voltage; the second factor allows for 6.7 per cent positive manufacturing tolerance in the lightning arrester, and the last factor allows the 25 per cent protective margin.

The lightning-arrester block voltage is, of course, dependent upon the maximum dynamic voltage rating of the lightning arrester.

This rating must be determined for the particular application by a careful analysis of the dynamic overvoltages to be expected due to unbalanced system faults and load rejection, including possible generator overspeed effects. If this formula and reasoning are applied to a 230-kv solidly-grounded system in which maximum dynamic overvoltages including harmonics are limited to 30 per cent above system maximum operating voltage to neutral, the indicated lightning-arrester rating is 182 kv, and the basic insulation level (BIL) required is 800 kv. This is just over 75 per cent of the present full-level BIL of 230-kv equipment

Figure 1. Transformer insulation and lightning arrester volt-time curves

and appears adequate for many important applications.

Because of the generally shorter times-to-crest of lower-magnitude traveling waves together with larger stacking factors when fewer lightning-arrester units are used, somewhat larger protective margins are probably desirable at the lower voltages. The following modification of the above equation may therefore be desirable:

$$\text{BIL} = (E_{avg} \text{ at } 5{,}000 \text{ amperes}) \times 1.067 \times 1.20 + 35 \text{ kv}$$

This equation allows a proportionally higher BIL at the lower voltages where the steep-front wave effects are more important, although generally largely offset by closer separation between lightning arrester and transformer.

A. M. Opsahl and E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): In our opinion, the industry as a whole is indebted to both Mr. Rorden and the laboratories of the Ohio Brass Company, for the material published in Mr. Rorden's paper. The lightning arrester will be the foundation stone of the basic insulation levels finally to be agreed upon by the triple joint committee on insulation co-ordination. Therefore the performance data relating to high voltage lines is of much interest.

Mr. Rorden's data on lightning arrester voltage characteristics as related to discharge currents agree well with results obtained in our impulse laboratories without transmission lines. This should be reassuring as to the use of laboratory data in the determination of the protected levels provided by lightning arresters.

In correlating lightning arrester voltages with apparatus withstand levels, it seems to us that the discharge conditions used to determine the lightning arrester voltage should be such that the voltage developed across the lightning arrester has about the same shape, as nearly as practical, as the voltage in terms of which the withstand strength of equipment is stated, so that the two are comparable. We suggest that the 1.5x40 voltage wave is a good basis for comparison because it has some duration and because it is a standard for equipment. We would like to point out that because a 1.5x40 voltage wave is used for equipment, a 1.5x40 wave of current should not be used to test lightning arresters because it does not produce a 1.5x40 voltage across the lightning-arrester terminals.

In the field, the voltage that is impressed across equipment protected by lightning arresters is first the voltage that appears up to lightning-arrester sparkover. This is the rate of rise of voltage impressed on the equipment. It is not the lightning-arrester discharge current that determines this, but the voltage caused by the lightning. In defining the withstand strength of apparatus, the 1.5x40 wave is used as a basis. After the lightning arrester has sparked, the lightning voltage also determines the lightning-arrester current, and Mr. Rorden's paper contains data from which it can be determined what these currents will be in stations whose incoming lines have a mile of overhead ground wire. After the voltage has risen to lightning-arrester sparkover, the voltage at the lightning-arrester terminals depends on the discharge current and the lightning-arrester characteristics. The 10x20 wave that now is used for lightning-arrester discharge characteristic tests produces a voltage wave across the lightning arrester that has a tail closely approximating the tail of the 1.5x40 wave. As Mr. Rorden points out, the crest of the lightning-arrester discharge voltage at a given current is higher with rates of rise of discharge current higher than that of the 10x20 current wave.

We are not at this time making a brief for a particular shape of lightning arrester test current or voltage, as we feel that this may well be a subject of considerable discussion. We do advocate that the approach to the discussion be realistic, giving due weight to the manner in which apparatus withstand strengths are stated and to the lightning-arrester duty expected in the field, on which the Rorden paper sheds light.

In the case of the high-current tests described by Mr. Rorden, made with a lightning arrester at the surge generator, the voltages and currents are quite steep and the lightning-arrester voltages shown for example in Figures 12 and 13 of the paper are steeper and rise higher than those in Figures 7 and 9, the latter being the field conditions, and Figures 12 and 13 being a test condition that does not find its counterpart in the stations described in the paper. Figure 9, for example, shows that the voltage at the lightning arrester does not rise faster than the voltage produced by the incoming voltage wave.

At all rates of rise of current, the crest of the lightning-arrester discharge voltage appears before the crest of the discharge current, and at the crest of the current the voltage has dropped, as shown in the volt-ampere curve of Figure 12. The opinion has sometimes been held by some that the lightning-arrester voltage stays at crest for a long time. That is not the case in the lightning-arrester discharge voltage nor in the 1.5x40 test wave, as has been evident for a long time from laboratory tests.

In considering the selection of a wave shape of discharge current for lightning-arrester testing, some thought also should be given to test facilities. It is practical to produce lightning-arrester discharge currents of reasonably high crests and some duration, enough to cause a discharge voltage approximating closely to a 1.5x40 wave. It also is practical to produce steep high currents of short duration. It is not practical to produce a current that is steep and high and also long. The difference between a 5,000-ampere current with a 5-microsecond front and a 5,000-ampere current with a 2-microsecond front is serious in high energy surge generators.

In conclusion we wish to say that we have no criticism of the Rorden paper, which we consider a concise and useful contribution. Our discussion is merely a commentary on the general subject treated in the paper.

P. L. Bellaschi (Consulting Engineer, Portland, Oreg.): One of the factors to consider in the protection of station equipment is the lead effect between the protective device and the apparatus protected. As indicated in (A) and (B) of Figure 2 of this discussion, leads and busses of the usual lengths encountered in stations can well be represented by a lumped inductance (L_1) and for the short times involved the transformer in effect is a capacitance (C_T). The problem is conducive to calculation. A 60-foot bus corresponds to about 20 microhenries and a large power transformer in the order of 1,500 to 2,000 micromicrofarads. For an incoming surge on the line appearing at the lightning arrester, rising to lightning arrester crest voltage E in 1 microsecond and limited to that voltage by the lightning arrester, the surge voltage e_T at the transformer is (for L_1 = 20 microhenries and C_T = 2,000 micromicrofarads)

$$e_T = \left(t - 0.2 \sin \frac{2\pi}{1.26} t\right) E, \text{ for } 0 < t < 1 \text{ microsecond}$$

$$e_T = \left(1 + 0.192 \cos \frac{2\pi}{1.26} t - 0.145 \sin \frac{2\pi}{1.26} t\right) E \quad \text{for } t > 1 \text{ microsecond}$$

Thus as shown in Figure 2(C), of this discussion, for an incoming surge rising to lightning-arrester crest voltage E in 1 microsecond and maintained by the lightning arrester at that voltage and for a 60-foot bus between lightning arrester and transformer terminating at the transformer, the surge voltage the transformer (e_T) is the lightning-arrester voltage (e_A) plus a superimposed oscillation 24 per cent above the lightning-arrester crest voltage (E), of a period T_1 = 1.26 microseconds. For a 120-foot bus, the voltage attained at the transformer would be 55 per cent above the lightning-arrester crest voltage, of a somewhat longer duration because of the greater inductance of the bus.

The voltage at the transformer depends on the ratio of the front duration to the period of oscillation of the bus inductance and transformer capacitance (T_3/T_1). The dissipative characteristics of the lightning arrester, the resistance of the bus and other circuit elements as well as the surge impedance of the line all contribute to reduce the crest voltage developed at the transformer. The oscillations superimposed in most cases will decay practically to zero in a matter of several oscillations.

Present-day knowledge of lead effects, lightning arresters, and station apparatus is reasonably comprehensive and quantitative. It has been applied effectively to station design. For example, to quote briefly from Report 317 of the International Conference on High-Voltage Electric Systems[1] presented in 1939:

"It is apparent that for effective protection and co-ordination of station apparatus against very steep impulses, consideration must be given to the circuit feet of leads connecting the various station parts and to the proper location of the protective devices. The most effective method is to mount the arresters on the transformers. Conditions in the station layout or due to the apparatus may not always permit this arrangement. In such cases, the lead voltage can be minimized by locating the arrester as close as possible to the transformer or apparatus it is intended to protect. A protector tube or suitable rod gap located at the line end of the station, will afford additional protection to the station apparatus against steep-wave-front impulses that may enter the station. The problems arising in protecting a large station against very steep

Figure 2 (above)

Figure 3. Impulse tests applied to transformer, full wave, chopped wave, and front of wave, and combination transformer-lightning arrester tests

Lightning arrester connecting to transformer through 40-foot lead (transformer withstand tests ASA and NEMA standards, 115-kv class)
e_A = voltage at lightning arrester;
e_T = voltage at transformer

voltages can be overcome by increasing the effectiveness of the overhead ground wire and the grounding (counterpoise) to the extent that the only possible voltages entering the station would be in effect impulse voltages of duration greater than 2 or 3 microseconds. It should be recognized that the presence of multiple lines, as well as the station capacitance, contribute beneficially and in no small measure to protection."

Another factor in protection at the shorter times arises due apparently to an inherent "delayed ionization effect" to rapid surge current discharge present in lightning arrester. It has the effect of accentuating the short time crest voltage developed at the transformer, as indicated in (D) of Figure 2 of this discussion. This effect has been apparent from the many impulse tests, commercial and experimental, that have been conducted since the middle 1930's in the various laboratories applied to transformers in combination with lightning arresters, such as illustrated in Figure 3 of this discussion. In this case, the voltage applied to the lightning arrester rises at the rate of 2,000 kv per microsecond, a value well in excess of what has ever been recorded in stations protected with overhead ground wire. The operation of the lightning-arrester gap is definite. Then follows a current inrush attaining 8,000 amperes approximately in less than 1 microsecond. As the result, the lightning-arrester voltage rises to 580-kv crest, then recedes in 1 microsecond to "normal" block voltage. Under these conditions the voltage at the transformer is a superimposed effect, due to the lead and lightning arrester, reaching well up to 850 kv, sustained for about 1 microsecond dropping to sustained or "normal" block voltage of the lightning arrester.

Because of their inherent strength at the shorter impulses,[1] transformers designed and tested in accordance with American Standards Association (ASA) (full and chopped waves) and National Electrical Manufacturers Association (NEMA) (front-of-wave) standards have been found well capable of withstanding combination tests of the character indicated. The lead and other short-time effects in relation to the volt-time characteristic of station insulation and to the over-all problem of station protection and co-ordination have been recognized and taken into account in station design, at least in certain quarters. However it is well that these problems be called attention to once again especially at this time and be re-examined particularly where reduced basic insulation levels are being applied. In the larger stations because of their extent and circuits involved, lead effects can become quite complex, requiring individual attention in each case. A certain amount of lead or bus between lightning arrester and transformer and between lightning arrester and other station equipment (circuit breakers) is permissible, the amount depending on the method of protection such as the use of overhead ground wire, the protective level and characteristics of the lightning arrester at short and long time, permissible lightning arrester tolerances, margins of protection, and volt-time characteristics and basic insulation level of the transformer and other station equipment.

The inherent "delayed ionization effect" due to rapid current discharge of the lightning arrester is clearly brought out in the tests reported by Mr. Rorden. This contribution sets forth and further emphasizes other important considerations that need be given attention in the application of arresters.

There remains a number of questions of fundamental character relating to station protection and co-ordination that require clarifying and rationalizing. Looking to the future here are a few suggestions on what need and can be done:

1. Present transformer levels are withstand and have no negative tolerance. Correspondingly, lightning-arrester protective levels should have no positive tolerances. Lately some progress has been made in this direction in an effort to reduce lightning-arrester tolerances to reasonable limits.

2. A closer correlation between lightning arrester and transformer impulse tests are very much needed. As they stand the two remain poorly co-ordinated. The transformer tests are hinged to the rod gap whereas protection is based more and more on the lightning arrester.

3. In connection with item (2), lightning-arrester voltage characteristics to a 3 or 2x20 microsecond current wave would be a logical addition or supplement to the present standards, inasmuch as a wave of this order has practical significance in protection and co-ordination.

4. The time has come for standardizing groups to consider basic insulation levels with reference to both the short and long duration impulses and to the wave forms of actual interest in protection, and not merely to the $1^1/_2$x40 microsecond voltage wave alone. Some progress has been made in this direction but more need be done to co-ordinate lightning arrester and equipment volt-time characteristics.

5. Additional improvement in the lightning-arrester 60-cycle dynamic and impulse characteristics coupled with effective methods of protection would pave the way to further rationalization in basic insulation levels and reduced levels, especially for applications to solidly grounded systems and at the higher voltages where economy is great.

6. The economics of protection in general need critical re-examining. For instance there seems to be little good justification in limiting line-type lightning arresters to voltages 73 kv and below. Because of their economic advantage this type of lightning arrester definitely has a place in the field of application to medium and even large power stations up to 115-kv to start with, and possibly even higher voltages eventually if such is found feasible.

7. To attain maximum economies in keeping with good engineering, we must avoid in planning and design pyramiding of conditions unlikely of simultaneous occurrence, which almost invariably will lead to unnecessarily higher costs. A more realistic approach to the problem of protection with a keen appreciation of probabilities is necessary.

2. Progress in Power-Transformer Insulation and Protection, P. L. Bellaschi. *Report Number 115*, International Conference on Large High-Voltage Electric Systems (Paris, France) 1946.

I. B. Johnson and **L. E. Saline** (General Electric Company, Schenectady, N. Y.): Mr. Rorden has added interesting experimental data on the performance of lightning arresters to traveling waves.

There are two statements made in the paper which we would like to amplify and comment upon:

1. "As the results of these tests were revealed, it appeared desirable to terminate the station end of the line with a capacitance comparable to that of a moderate-size station. Such capacitors were not available, but it is believed that their effect would be to increase the oscillatory nature of the voltage at the station in Figure 9(B)."

To determine the nature and magnitude of these oscillations as a function of terminal capacitance, an analysis (based on an extensive study to be reported subsequently) was made of Mr. Rorden's test circuit. This analysis was verified and extended on the transients analyzer by setting up in miniature the equivalent of Mr. Rorden's test circuit (a lightning arrester located 200 feet from the end of a line) as shown in Figure 4 of the discussion. The wave shape applied to this miniature circuit is shown on Figure 5 of this discussion, and is compared with the voltage across the lightning arrester at the station end as shown in Figure 7(A) of Mr. Rorden's paper. The application of this impulse to the miniature circuit gave the results at the open end of the line as shown in Table I of the discussion. For comparison the data obtained by Mr. Rorden as read from Figure 9(B) is included and shows good agreement for period of oscillation, magnitude of oscillatory overshoot, and number of cycles before the oscillatory voltage is completely damped. Upon terminating the miniature line with various lumped capacitances up to 5,000 micromicrofarads, the voltage at the capacitor increased to a maximum of 183 per cent of the voltage across the lightning arrester (for $C_T = 3{,}500$ micromicrofarads) as shown in Figure 6 of this discussion. Thus the transient analyzer studies of the miniature circuit show agreement with the results obtained in Mr. Rorden's staged tests for the open terminal case and have extended Mr. Rorden's study to show that the voltage at the line terminal is a function of the terminating capacitance and can increase considerably above the level held by the lightning arrester. Furthermore, the magnitude of the oscillatory over-voltage also is a function of the voltage wave shape at the lightning arrester and the separation between the lightning arrester and the protected apparatus.

Although the oscillatory voltages reported in Figure 6 of this discussion can be obtained for pure capacitance, somewhat lower values can be expected due to the inherent damping present in terminal apparatus represented by the lumped capacitance or due to surge impedance where relatively long lines (1,000 feet or more) are concerned.

For a lightning arrester located on the line 200 feet away, Mr. Rorden comments as follows:

2. "The crest of the first oscillation is higher than the level when the lightning arrester is located at the station end, but the average level is approximately the same."

Laboratory tests indicate that oscillations superimposed on the regular full wave impulse cannot be averaged out—cannot be neglected. Their effect on the insulation is that to be expected from an equivalent increased voltage applied to the insulation.

Therefore, in the application of lightning arresters it is desirable that they should be placed as close as possible if not directly across the apparatus being protected to eliminate or to reduce as much as possible the causes for the oscillatory over-voltages.

William L. Teague (Westinghouse Electric Corporation, Sharon, Pa.): In recent months the established basic insulation levels have been studied by several groups for the purpose of improving them and providing better standards for the industry. In his paper, Mr. Rorden has presented test data on lightning arresters under simulated service conditions, and an analysis of insulation levels from the user's viewpoint based on lightning-arrester performance. These are valuable contributions to the solution of the problem. There are two considerations that I would like to mention.

The first is the importance to the industry from both the manufacturer's and the user's viewpoint, of having and using standardized insulation levels. Even though most large transformers are specially designed, with the insulation levels standardized in steps, definite methods of constructions with particular interleavings of insulation and even standard drawings can be used. These can be developed and improved so that the end results are economy and quality. Both of these advantages should appeal to the user as well as the manufacturer. To reap the greatest benefit, the voltage steps must be large enough so as not to overburden the manufacturers with too many classes and yet small enough that a large majority of the users can and will conform to the standard classes.

The second thing I would like to say is to sound a warning against setting the insulation levels too low. Experience has shown

Figure 5. Voltage wave shape across lightning arrester

Figure 6. Capacitor voltage versus terminal capacitance as obtained on transient analyzer

that it is sound engineering to reduce insulation one class below line voltage on effectively grounded systems in the range of 138 to 230 kv. As manufacturers we were among the first to advocate reducing insulation levels for the higher voltage classes more than one class. During the past year the appeal of the economy that might result from reducing insulation has been so great that we have had to rigidly set minimum levels below which we would not design. There are many factors that enter into the problem including the normal frequency operating voltage. Some of these cannot be evaluated except by experience. Also many variables that are difficult to control should be considered. In the application of lightning arresters alone small variations in installation practices may result in considerable differences in the voltage level at the equipment. A good example of this is Figure 16 in the paper. "A" shows the lightning arrester located at the station and a voltage of 321 kv. "B" shows the lightning arrester 210 feet from the station with a T-tap connection and the voltage at the station is 395 kv, or 23 per cent greater. "C" shows the lightning arrester 210 feet from the station with hairpin tie and a voltage at the station of 346 kv. Just the difference of a T-tap and a hairpin tie makes 14 per cent difference. Such variations that may result from differences in practices of various users of equipment must be considered in setting up insulation levels. All of the factors that enter into the problem should be considered, and total risk to equipment and to service balanced against the saving in cost. It would be poor economy indeed to permit the pendulum to swing too far in the reduction of insulation levels with an ever increasing demand for more reliable and dependable service.

W. A. McMorris, S. B. Howard and J. R. Meador (General Electric Company, Pittsfield, Mass.): Mr. Rorden is to be complimented on the test program reported in the paper. We agree with the viewpoint that equipment impulse insulation levels should be based on the protective levels afforded by lightning arresters, and agree with the three generalized factors for establishment of those levels which Rorden has enunciated in the section headed "About Lightning Arresters."

Regarding the selection of lightning-arrester voltage rating, it is fundamental that this rating be at least equal to the maximum line-to-ground dynamic voltage expected at the lightning-arrester location under any condition of operation, including load rejection and line-to-ground faults. Any compromise with that principle not only jeopardizes the lightning arrester, as Rorden points out, but, even more important, jeopardizes the equipment to be protected by introducing the possibility that overvoltage failure of the lightning arrester will remove protection from the equipment at the very time it is most needed—during the critical period when there is lightning on the system and the chance of getting additional strokes is prevalent. The statement in the paper: "This (lightning arrester) initial breakdown voltage is above most switching surges at the bus, so that it commonly requires lightning to set off the lightning arresters. . . . at the instant the excessive dynamic voltage is impressed. . . ." is open to question. Lightning arresters do frequently operate from switching surges; in fact, lightning arresters generally operate to limit switching surges to the level of 2 to 3 times normal line-to-neutral voltage. At any rate, it would not be sound engineering to ignore the strong possibility that lightning arrester discharge may be initiated by either switching or lightning at the same time that dynamic overvoltage conditions exist at the lightning-arrester location. This means that the dynamic overvoltage must be taken into account when selecting the lightning arrester rating.

In the section headed "About Lightning Waves," Rorden states, ". . . . if the (ground wire and low station-and-tower-footing impedance) combination is adequate, steep fronted direct strokes are eliminated from the station." He then goes on to calculate the traveling-wave voltages and currents which must be taken care of by the station lightning arresters in protecting the station apparatus. It appears to us to be more logical to base protection on the discharge currents measured in service through lightning arresters in stations, regardless of how these discharge currents are produced, that is, whether by direct strokes or by traveling waves. Some groups have questioned whether or not the 10x20 microsecond current wave, which appears in the present lightning arrester standards and which has been used for comparing lightning-arrester performance characteristics, is representative of the more severe discharges encountered in service. To answer this question, the Lightning Protective Devices Subcommittee is at present studying all available information on discharge currents through lightning arresters in service, with the object of evaluating the currents and wave shapes on which insulation co-ordination may most reasonably be based.

With regard to the section headed "Tests of Lightning Arresters," the lightning-arrester discharge voltage, for a current of given crest value and wave shape, is the same whether or not the discharge current arrives at the lightning arrester over a line impedance. The lightning-arrester discharge voltages obtained in Rorden's tests are in close agreement with results of our laboratory investigations, using currents of the same crest value and wave shape.

Rorden's test results on the effect of line inductance between lightning arrester and protected apparatus, in producing oscillatory voltages in excess of the lightning-arrester discharge voltage level, are comparable to the test results reported by K. B. McEachron in 1929.[1] Reference to that work shows that the voltage held at the apparatus terminals is increased to almost twice lightning arrester discharge voltage by the introduction of an inductance equivalent to 100 feet of overhead line between lightning arrester and apparatus terminals, with steep front surges applied. Both series of tests point to the necessity for installing lightning arresters in close shunt relationship to the apparatus they are intended to protect, if full advantage is to be gained of the protective levels available at the lightning arrester terminals.

With regard to the physical connection between line and lightning arrester, the "hairpin" or V-connection reduces the lightning arrester lead impedance drop, which appears at the protected apparatus terminals, below that obtained with the conventional T-connection. The advantage of the V-connection was called to the attention of the industry in 1931[2] and we have advocated it for many years.

The conclusion in the paper regarding the proportionality of discharge voltages obtained with "unrestrained" currents and different numbers of lightning-arrester units in series appears to us to be questionable. Since the surge voltage applied over the line was held constant in Rorden's tests, the lightning-arrester discharge currents would have different crest values and different rates of rise, which would result in different crest discharge voltages per unit, depending on the number of lightning-arrester units in the stack. With the surge current held constant, the lightning-arrester discharge voltage would have been proportional to the number of units in the stack.

Under "Line-Type Lightning Arresters," the statement is made that ". . . . the protective level of the line type is less than 10 per cent above the station lightning arrester (of equal rating)." This statement does not agree with the lightning-arrester performance values given in the Lightning Protective Devices Subcommittee report, Performance Characteristics of Lightning Protective Devices[3] which shows that line-type lightning arresters have discharge voltage 20 per cent above that of station-type lightning arresters at 5,000 amperes (10x20 microseconds) and even higher differentials at higher currents.

The thought expressed in Rorden's paper, that there should be a large number of small steps in the basic impulse insulation levels, should be taken with caution. Even though large high-voltage power transformers are not built on a production line, a considerable amount of standardization in design and manufacture has been achieved. For that reason, each element of the insulation structure must be carefully evaluated as to its effect on the whole. The number of insulating barriers, for example, cannot normally be changed in less than 10 to 20 per cent steps. The same is true to a lesser degree of turn insulation and oil-duct sizes. These "building blocks" can be and are standardized with resultant improvement in quality and reduction in cost. If the basic insulation levels are selected to fill the needs of the majority of users, the ultimate benefits of standardization will accrue to these users. Minor variations from the standard levels will not result in proportionate cost savings.

Harold L. Rorden: The question of location of lightning arresters with respect to protected equipment apparently is one of uppermost concern. In these tests the

lightning arresters have demonstrated their ability to maintain adequate protective levels at their terminals. When the lightning arrester is placed some distance from the protected equipment, the resulting loop circuit contains a combination of impedances which is likely to result in oscillatory voltages because the resistance of the lightning arrester falls below critical damping. The resultant voltage at transformer terminals will therefore probably be somewhat higher than that at the lightning-arrester terminals during the crest of the first half cycle of a highly-damped high-frequency wave. Analytically this potential might reach twice that at the lightning-arrester terminals, but other factors reduce the probability of obtaining such potentials to a rather remote possibility.

The oscillograms of Figures 9 and 10 of the paper illustrate the oscillatory nature and the magnitudes of voltages that might be impressed on a transformer as were obtained during the test. Figure 7 of this discussion compares the worst oscillatory voltage obtained by test at the station end (transformer terminals), with the protective level provided by the lightning arrester at the end of the line without added capacitance. A curve of transformer insulation having a strength of about 165 per cent of the minimum level at 1/2 microsecond also is given for comparison. This curve is plotted from commonly accepted data for a basic insulation level of 450 kv, which is one step reduced from presently recognized practice for 115-kv service and is about 82 per cent of the full-rated basic insulation level (550 kv). With the lightning arrester 200 feet away, the margin of protection at the first crest of the oscillatory voltage with 1,600-micromicrofarad capacitance at the station end is approximately 22 per cent. The margin of protection afforded by the lightning arrester without added capacitance at the station end is much greater at the short times, but more nearly parallels that of the transformer insulation for times beyond 4 microseconds. In this longer time area the margin of protection, even with the insulation reduced one step, is about 65 per cent. An ideal protective curve would be one that parallels the transformer insulation providing a uniform margin throughout. A protective curve plotted through the crests of the oscillatory voltage at the station with the lightning arrester 200 feet away, and with one step reduced basic insulation levels indicates a fair margin at any point in the curve. The curve of voltage at the lightning arrester terminals might well be said to provide more than necessary margin at the short times. Mr. Starr's data indicate that the protective curve with the lightning arrester at 50 feet is a fair parallel of the insulation strength, and that greater distances are tolerable if adequate margin is provided.

It appears therefore that although the greatest margin is unquestionably obtained by placing the lightning arrester close to the protected equipment, it is not of extreme importance to do so because of the nature of insulation strength in the short time range. When lightning arresters are mounted directly at the transformer, circuit breakers, particularly in large stations, may be a considerable distance away from the lightning arrester and therefore subject to rather severe surges. Circuit breakers also add capacitance to the station and can contribute to causing surges to become oscillatory at their terminals. In service, conditions, as mentioned by Mr. Bellaschi, are probably somewhat better with respect to limiting the oscillatory nature of overvoltages due to the distributed nature of station capacitance. Also where more than one line terminates at the bus, voltages are not doubled by reflection and will, in fact, be reduced below the level of the incoming surge at stations having three or more lines terminating at the bus. In two Bonneville 230-kv stations in the lightning area lightning arresters have not operated since the stations have been completed. One of these stations contains four transformer banks and two lines terminating on the bus. The other contains two transformer banks with seven lines terminating on the bus. Lightning hits have occurred to conductors close to these stations, but to date these hits have not resulted in lightning-arrester operations. The lightning arresters are equipped with counters one of which was checked during the Barberton tests and found to be in perfect working order.

Figure 7. Voltages at station end and transformer insulation strength

97-kv station-type lightning arrester, 450-kv insulation class

Figure 7 of this discussion replies to Messrs. Johnson and Saline's statement that the oscillatory voltages cannot be averaged. The average level determines adequacy of protection at the longer times.

The agreement with laboratory tests reported by Messrs. McMorris-Howard-Meador, Opsahl-Beck, and Johnson-Saline is of particular interest in lending confidence to laboratory tests that attempt to duplicate service conditions. The tests at Barberton were conducted with a transmission line in order to minimize doubts that otherwise arise when service conditions are simulated. Once such tests have been conducted and duplicated by laboratory equivalents, further laboratory studies can be carried on with complete confidence. It is well known that traveling-wave phenomena can be accurately translated in terms of circuit constants and that transmission lines can be simulated in the laboratory.

Complete agreement is given with Messrs. Opsahl and Beck that realistic test waves should be adopted that are not difficult to obtain in the laboratory and that will provide the user with information that applies to conditions in service. It seems probable that one such test wave is inadequate because of extreme differences that may exist in transmission systems, such as use or absence of overhead ground wires for station protection.

We also agree with Mr. Teague that all factors affecting basic insulation levels must be considered in establishing insulation levels and that steps should be so chosen that they are large enough for economic design, yet small enough so that the user will not be tempted to go off standard in the interests of economy.

Mr. Starr's suggestion of an 800-kv basic insulation level for 230-kv operation represents an insulation level equal to 75 per cent of presently recognized practice. The tests have shown that a 75-per cent lightning arrester can adequately protect a 75-per cent basic insulation level, and recent NEMA recommendations suggest 75-per cent lightning arresters as the basis for selecting insulation levels for 230 kv. An 800-kv basic insulation level for 230-kv operation would effect substantial economies and appears satisfactory for many solidly-grounded systems.

Mr. Bellaschi's comment relative to delayed ionization is significant, since it indicates that some variable besides current is present in determining the resistance characteristic of lightning arresters. Mr. Bellaschi's summary of needs for further study of this subject is very complete and appropriate.

Messrs. McMorris, Howard, and Meador's statement that the number of lightning arrester units would be proportional to voltage if the current were kept constant is questionable, and published catalog data of lightning arresters do not so indicate. On the basis of lightning-arrester catalog data, the increase of discharge voltage per unit during the tests corresponds to 100 per cent increase in current. The actual current increase was about 25 per cent.

Analogue Computer for Multicomponent Fractionation Calculations

G. W. GOELZ
ASSOCIATE AIEE

J. F. CALVERT
FELLOW AIEE

IN THE petroleum and natural gas industries rather tedious trial-and-error computations have been employed in designing and predetermining the performance of multicomponent fractionating columns. The purpose of this paper is to describe an analogue computing machine, Figure 1, with the aid of which these calculations are carried out in approximately one-tenth the man-hours required for the more usual methods. A description of the physical operation of a fractionating column and a development of the equations applying to this operation will be presented. Following this, a description will be given of the computing machine and its principle of operation.

The Problem

A fractionating column, or tower, is a type of equipment which permits a liquid stream to cascade down over a series of trays or plates, Figure 2, and allows a vapor stream to bubble up through the plates countercurrent to the liquid stream. The feed stream (containing several components, such as ethane, propane, butane, and so forth) enters the column somewhere between the top and bottom plates. Often this stream is introduced about halfway up the tower. Each of the components of the feed is present in varying amounts in the liquid stream falling from a given plate and the vapor stream rising from a given plate. The relative amounts of the several components in a given stream leaving a specified plate within the column depend upon several factors including the temperature and pressure of that stream and the relative amounts of liquid and vapor components in the streams approaching and leaving the plate. In general the liquid stream as it cascades down the column from top to bottom contains increasing amounts of the less volatile components and decreasing amounts of the more volatile components. Conversely, the vapor stream in passing up the column becomes poorer in the less volatile components and richer in the more volatile ones. In this manner the feed, which contains substantial quantities of each of the components, is separated into a vapor product, which primarily consists of the more volatile components, and a liquid product which predominately contains the less volatile components. The vapor product leaves the top plate and the liquid product is withdrawn from the bottom one. In order to effect this separation it is necessary to maintain substantial liquid and vapor flows within the column. This is achieved by utilizing a heater to introduce heat into the bottom chamber, and using a cooler or condenser to remove heat at the top of the column (through which part of the vapor product is passed to produce a liquid stream which is recycled to the top of the tower).

The quantitative relationships between the compositions, quantities, temperatures, and pressures of the various liquid and vapor streams include material balances, enthalpy (or heat) balances, and equilibrium conditions. These relationships represent the performance of a fractionating column operating under steady state conditions as indicated in Figure 2. Consider that section of the column within the dashed line. Applying the foregoing relationships to this section:

1. The total mass of material entering the section is equal to the total mass of material leaving.
2. The mass of any one component entering the section is equal to the mass of that component leaving.
3. The enthalpy of entering streams plus any enthalpy added (as in the heater) is equal to the enthalpy of the leaving streams.
4. The composition of any vapor stream rising from a plate is in equilibrium with and at the same temperature as the liquid falling down from that plate.
5. The temperatures and stream quantities vary throughout the fractionating column in such a manner that the above conditions are met. In general, the pressure is fairly constant from plate to plate.

The detailed calculations may be made as follows:

1. Obtain the rate of flow and composition of the liquid bottom plate product.
2. Obtain the rate of heat input from the heater.
3. Obtain the column operating pressure.
4. Determine by trial and error the bottom plate temperature.
5. Calculate the composition of the vapor stream leaving the bottom plate.
6. Calculate the net enthalpy input to the bottom of the column (heater input less enthalpy of liquid bottom product).
7. Consider an envelope (similar to that represented by the dashed line in Figure 2) enclosing the bottom plate and the heater.

Paper 50-15, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 31, 1949; made available for printing November 22, 1949.

G. W. Goelz and J. F. Calvert are with Northwestern University, Evanston, Ill.

Figure 2 (left). Schematic diagram of a multicomponent fractionating column

Figure 3(A) (right). Curves of $h_i(t)$ and $H_i(t_r)$

8. Using enthalpy balances, material balances, and equilibrium relationships, together with the data obtained in steps 4, 5, and 6, determine by trial and error the temperature, composition, and rate at which liquid leaves the second plate and the rate at which vapor rises from the bottom plate.

9. Calculate the composition of the vapor stream leaving the second plate.

10. Repeat steps 7, 8, and 9 for each plate between the bottom of the column and the feed plate.

11. Follow a similar procedure for the top section of the column by calculating down from the vapor product.

The calculations which are made upward and those which are made downward along the column are very similar in character, and the computing machine to be described may be employed for both. Therefore, for the sake of brevity, only upward computational procedures will be described here.

At this point reference should be made to the glossary. Consider plate r in Figure 2 and the volume enclosed by the

Figure 3 (left). Functions represented by the computer

Figure 3(B) (right). A typical $K_i(t)$ curve

Figure 4. Computer block diagram

dashed line. For computations made upward, the equations to be solved when a problem involves n significant components are:

For equilibrium between the liquid and vapor streams leaving a plate

$$\sum_{i=1}^{i=n} [a_i V + b_i] K_i(t) - \sum_{i=1}^{i=n} [a_i V + b_i] = 0 \qquad (1)$$

For enthalpy balance,

$$\sum_{i=1}^{i=n} [a_i V + b_i] h_i(t) - \sum_{i=1}^{i=n} a_i V H_i(t_r) + Q = 0 \qquad (2)$$

The usual procedure is to assume a pair of values of V and t, and substitute in equations 1 and 2 to see if the equations are satisfied. If they are not, the procedure is repeated until the equations balance. In this process the functions, $K_i(t)$, $h_i(t)$, and $H_i(t_r)$, are obtained from graphs, see Figure 3. When those values of V and t have been found which simultaneously satisfy equations 1 and 2, new values of the coefficients, here called a_i', are obtained for the calculations to follow.

$$a_i' = \frac{[a_i V + b_i] K_i(t)}{\sum_{i=1}^{i=n} [a_i V + b_i] K_i(t)} \qquad (3)$$

The terms on the right side of equation 3 are taken from the preceding data. In order to proceed one more plate up the column, a new bounding surface, represented by the dotted line in Figure 2, is assumed which encloses the preceding volume and also the next plate above. To solve for the conditions associated with this next plate, equations 1, 2, and 3 are solved again. This time t_r is the temperature determined as t from the previous solution of the equations and the a_i values are those previously calculated as a_i' from equation 3. Calculations are made upward along the column in this fashion.

It is from this sequential procedure that the descriptive term plate-to-plate calculation is taken. The methods are described more fully in chemical engineering publications.[1]

The Analogue Computing Machine

Primarily, the computing machine is composed of resistors, potentiometers, and amplifiers, suitably chosen and connected to yield the electrical representation of the preceding equations, though in slightly modified forms. A 400-cycle carrier voltage is applied to a number of channels. One channel is required for each chemical component to be represented; and while six are provided in the present machine, this is not a basic design restriction. Each

Figure 5 (below). Multiplication circuits

Figure 6 (right). Addition circuit

channel is composed of a number of circuits, along which the voltage is multiplied by the appropriate factors. At various locations, voltage signals are added and subtracted as required by the plate-to-plate equations. Figure 4, which illustrates a section of the machine in block diagram form, will be discussed later in some detail.

For the computational procedures employed with the machine, equations 1, 2, and 3, respectively, are treated in modified forms as follows

$$\sum_{i=1}^{i=n} \frac{1}{2.07}\left[E(-a_i)\frac{V}{N_1}+E\left(-\frac{b_i}{N_1}\right)\right]\times (-2.07)(-N_{2i})\frac{K_i(t)}{K_i(t''')}\frac{K_1(t''')}{N_{3i}}+ \sum_{i=1}^{i=n}\frac{1}{2.07}\left[E(-a_i)\frac{V}{N_1}+E\left(-\frac{b_i}{N_1}\right)\right]\times (-2.07)=0 \quad (1A)$$

$$\sum_{i=1}^{i=n}\frac{1}{2.07}\left[E(-a_i)\frac{V}{N_1}+E\left(-\frac{b_i}{N_1}\right)\right]\times (-2.07)\frac{h_i(t)}{h_i(t''')}\frac{h_1(t''')}{1{,}000}+ \sum_{i=1}^{i=n}E(-a_i)\frac{V}{N_1}\frac{H_i(t_r)}{1{,}000}+E\frac{Q}{1{,}000}=0 \quad (2A)$$

$$a_i'=\frac{\frac{1}{2.07}\left[E(-a_i)\frac{V}{N_1}+E\left(-\frac{b_i}{N_1}\right)\right]\times (-2.07)\times(-N_{2i})\frac{K_i(t)}{K_i(t''')}\frac{K_1(t''')}{N_{3i}}}{\sum_{i=1}^{i=n}\frac{1}{2.07}\left[E(-a_i)\frac{V}{N}+E\left(-\frac{b_i}{N_1}\right)\right]\times (-2.07)(-N_{2i})\frac{K_i(t)}{K_i(t''')}\frac{K_1(t''')}{N_{3i}}} \quad (3A)$$

Here, E is the magnitude of the input voltage carrier, the term $1/2.07$ is introduced by the circuit procedures employed for addition and subtraction, and terms such as N_1, N_{2i}, and $1/1{,}000$ permit certain design and constructional simplifications.

It is required for the satisfactory solution of equations 1A through 3A that the machine:

1. Represent the algebraic operations of addition, subtraction, and multiplication.
2. Represent, at least piece-wise, the data given on curves similar to those illustrated in Figure 3.
3. Provide for the independent insertion and variation of V and t at the discretion of the person operating the machine.
4. Combine all terms in such a fashion that the operator is presented with a measure of the balance or lack of balance in equations 1A and 2A, which result from his assumed values of V and t.
5. Provide data for the determination of the a_i' terms.
6. Place reasonable bounds on the equipment errors.

Representation of Algebraic Operations

Multiplication is performed either by means of a voltage divider network or a voltage amplifier. Where a voltage divider network is employed, the multiplying factor (voltage gain), α, is limited to positive values less than unity; but where an amplifier is used the multiplying factor β may be either negative or positive, depending upon whether the amplifier does or does not invert respectively, and the magnitude of β is limited to the maximum amplifier gain, which in general, is greater than unity. Figure 5 shows the typical circuits used for multiplication.

Both addition and subtraction can be represented through the circuit of Figure 6.[2] The 400-cycle voltages that are 180 degrees out of phase with respect to the positive reference voltage subtract, effectively, from the voltages in phase with the reference. In some cases, a voltage proportional to, but not necessarily equal to, the sum of the input voltages may be required. For these cases, the amplifier of gain G, see Figure 6, can be eliminated.

Piece-Wise Representation of Curve Data

A number of terms in the plate-to-plate equations are functions of either the known temperature, t_r, or the unknown temperature, t. The machine represents each of these by the over-all voltage gain of a voltage divider and amplifier arranged in cascade. The particular temperature at which a function is evaluated is represented by the angular position of a potentiometer located within the voltage divider. Each of the voltage divider-amplifier circuits is employed to represent a section of a given curve bounded by two chosen temperature limits, t' and t'''. Temperature bounds are selected by the operator with due regard given to the limitations of the machine and to the probable range of temperature needed in any given solution.

The functions of temperature, which the computer must represent, fall into two general classes. They are the almost linear functions, which are treated as linear over limited temperature ranges, and the approximately semilogarithmic and, hence, nonlinear functions. The $H_i(t_r)$ and $h_i(t)$ functions are of the first type while the $K_i(t)$ functions are of the second.

The circuit of Figure 7 could be used to represent the curves of Figure 3(A). The potentiometer indicated in the circuit is linear. If R_3 is adjusted to a resistance such that $R_3G/(R_1+R_3)=h_i(t')/1{,}000$ with $G=h_i(t''')/1{,}000$, the angular position of the potentiometer dial between θ' and θ''' can be calibrated linearly in terms of temperatures between t' and t'''. The over-all gain of the circuit, e_3/e_1, is then equal to $h_i(t_r)/1000$, when the dial is positioned at any specific temperature setting, t_r. Similar circuits are required to provide gains equal to $H_i(t_r)/1000$ when individual temperature dials are adjusted to read t_r, see equation 2A.

The 100 pounds per square inch absolute curve of Figure 3(B) can be approximated by the circuit of Figure 8.[2] Except that resistor R_3 has been added, the circuit of Figure 8 is identical to that of Figure 7. When the dial of the linear potentiometer R_1 is linearly calibrated, G, R_2, and R_3 can be adjusted such that the circuit will provide a function which, within a selected temperature range, closely approximates and at three points coincides with the desired curve. It is possible to draw two sets of curves of $K_i(t')/K_i(t''')$ versus $K_i(t'')/K_i(t''')$ with R_2 and R_3 as parameters. These curves may be referred to in choosing the approximate values of R_2 and R_3. A bridge type calibration circuit, to be described later, allows the operator to establish R_2 and R_3 exactly. The over-all gain of the voltage divider is made equal to $K_i(t')/K_i(t''')$ by adjusting R_2 with the potentiometer set to θ'. In like manner the over-all voltage divider gain is set equal to $K_i(t'')/K_i(t''')$ by varying R_3 with the potentiometer wiper positioned at θ''.

In the actual circuit, Figure 4, the voltage divider of Figure 8 is preceded by an inverting amplifier of gain N_{3i}. Thus, the

Figure 7 (left). Multiplication by a linear function of t

Figure 8 (right). Multiplication by a nonlinear function of t

gain of the amplifier following the voltage divider is set to $K_4(t'')/N_{21}$. This design arrangement permits the machine to accommodate a wide range of values of $K_4(t'')$, and at the same time leads to a standardization of parts.

The closeness with which the curve is approximated depends upon the magnitude of the ratio $K_4(t')/K_4(t'')$. The error in fitting a curve can become rather large for small values of this ratio. However, the operator may easily keep the error involved in representing the K functions to within three per cent by proper choices of the pair of temperatures t' and t''. For flat K curves, a 100 degree Fahrenheit temperature range can be chosen, while for very steep K curves a 50 degree range may be required.

Independent Insertion of V and T

The computer represents V/N_1 as the over-all gain of a single potentiometer. Once a problem is put into the machine, the variable t is represented by the angular position of a ganged potentiometer shaft. Thus, by merely varying two knobs, the operator inserts successive, independent trial values of V and t until the machine indicates that a particular pair of settings satisfies the two plate-to-plate equations.

For a 6-component machine, a trial setting of the ganged potentiometer shaft must cause the insertion of 12 functions of t evaluated at the trial temperature setting. Six of the functions are of the linear class shown in Figure 3(A) and six are of the nonlinear class indicated in Figure 3(B). The first six functions are traced out by six circuits similar to that of Figure 7, and the second six are represented by six circuits similar to that of Figure 8. Thus, for a 6-component machine, the ganged potentiometer shaft mounts 12 linear potentiometers.

Combination of Terms and Representation of Equations

The line diagram of Figure 4 indicates how the machine is employed to represent the plate-to-plate calculations. The voltage gains existing throughout the circuit, when a solution has been obtained, are shown on the diagram. The voltage magnitudes that exist at the marked points indicated on Figure 4 are given in the following terms (an asterisk indicates that a voltage does not have the magnitude specified unless a solution has been obtained).

Point 1. E

Point 2. $E\,\dfrac{V^*}{N_1}$

As indicated earlier, a 400-cycle voltage of magnitude E is applied to the signal circuit input. Since E appears in each term of equations 1A and 2A, the oscillator voltage control can be used to vary the voltage level throughout the computer signal circuits. The best signal to noise level is obtained when the voltage level is just below the point at which any one of the amplifiers is overdriven. In the interest of maximum accuracy, the optimum voltage level must be established prior to every solution on the machine. Beyond the input, amplifiers and voltage dividers are placed in the circuits at locations where the voltage signal is to be multiplied by a new factor. Where addition or subtraction must take place, a circuit similar to that of Figure 6 is used. Minus signs are taken care of by inverting amplifiers. A pair of null indicators provide the operator with a measure of the unbalance of the plate-to-plate equations.

Determination of Data Required for Solution of an Adjacent Plate

The sequential character of the plate-to-plate calculation was indicated previously. Part of the information obtained from the calculations made for one plate is employed in the calculations to be made for the next. This procedure will now be discussed with particular reference to the computing machine.

The a_i' coefficients, obtained from the calculations at one plate through the use of equation 3A, become the corresponding a_i coefficients for the calculations to be made at the next plate through the use of equations 1A and 2A. Referring jointly to equation 3A and to the preceding formulas for calculating voltage magnitudes, it will be found that the numerator of the equation appears in the appropriate computer channel as the magnitude of the voltage output of an *A8* amplifier. This voltage may be measured. The denominator of equation 3A is equal to the sum of the output voltages of all the *A8* amplifiers. When all the *R* resistors, Figure 4, which connect the *A4* amplifiers to the input of the Null 2 Indicator, have been disconnected, a voltage may be measured at this input location which is proportional to the sum of the output voltages of all the *A8* amplifiers.

The temperature, t, obtained from the calculations at one plate becomes the temperature, t_r, to be employed in equation 2B for the calculations at the next. The temperature, t, can be read for the appropriate plate from the t dial setting on the computing machine, see Figure 4.

Discussion of Potential Errors

To a large extent, the precision with which the operator can set the voltage gains (amplifiers and voltage dividers) controls the accuracy of the algebraic operations performed by the computer. The percentage error introduced in setting the voltage gain of a linear potentiometer by means of a calibrated dial would vary inversely with the voltage gain to be set. Because of this fact, calibrated dials are not employed for this purpose. Instead, all computer gains are established with the aid of a bridge circuit, see Figure 8 for a block diagram. The error signal is displayed simultaneously on ten dual *6AF6-G* tuning eyes so placed on the front of the panel that one is always in view for the operator. Each of the dual eyes simultaneously displays a high and a low sensitivity range. By means of these, voltage gains can be set to within 0.5 per cent.

Certain answers appear on the machine as voltage magnitudes. A voltmeter permits these to be read with an accuracy of better than 0.5 per cent.

The greatest source of error is in the representation of the semilogarithmic functions. With the selection of temperature range now employed, this potential inaccuracy can be kept below three per cent.

Summary

There appears to exist in the oil industry a definite use for a computing machine which may be employed to shorten the multi-component fractionation plate-to-plate calculations.

A machine believed to be of satisfactory accuracy and reliability has been designed and is in operation. It is estimated that it reduces the computing man hours to about ten per cent of that of the former procedures.

The machine can be employed not only on the design of new equipment, but also on the study of possible design and feed variations which might be made in existing fractionation columns.

Glossary

In equations 1, 1A, 2, and 2A it is assumed that: the desired flows of the components in liquid form through the bottom plate of the column are known; the desired net heat flow into the lowest chamber is known; and calculations have been carried upward through the rth plate and the chamber immediately above it. Therefore, from these conditions data are to be computed for plate $(r+1)$ and for the chamber immediately above the latter.

Equations 1 and 2 represent the material and the enthalpy balance established, under steady-state conditions, between the volume enclosed by the bounding surface represented by the dashed line in Figure 2 and the region outside of that volume.

Liquid Flows Per Unit of Time

L = total number of moles of liquid for all of the i components descending from the reference plate, r.

l_i = number of moles of liquid in the ith component of L.

b_i = number of moles of liquid in the ith component which is being withdrawn through the bottom plate of the column.

Vapor Flows Per Unit of Time

V = total number of moles of vapor for all of the i components rising through plate $(r+1)$.

v_i = number of moles of vapor in the ith component of V.

Steady-State Temperatures

t_r = temperature of the components (in both liquid and vapor form) on and immediately above plate r.

t = temperature of the components (in both liquid and vapor form) on and immediately above plate $(r+1)$.

t' = lower limit of the temperature range for a specific operating arrangement of the machine.

t''' = upper limit of the same temperature range (see t').

$t'' = (t'+t''')/2$.

t_g = a general term = a dial setting representing temperature.

Enthalpies

$h_i(t)$ = enthalpy per unit mass of l_i at temperature, t.

$H_i(t_r)$ = enthalpy per unit mass of v_i at temperature, t_r.

Q_1 = enthalpy input to bottom plate of column from heater.

Q_2 = enthalpy of the liquid stream leaving the bottom plate.

$Q = Q_1 - Q_2$.

Ratios

a_i = moles of vapor in the ith component of vapor rising through plate $(r+1)$ divided by V.

a_i' = defined similarly to a_i except with respect to plate $(r+2)$.

$K_i(t) = \dfrac{v_i/V}{l_i/L}$ and is a function of temperature, t, and of the pressure.

Voltage

E = magnitude of the 400-cycle signal voltage applied to the input of the computing machine.

Resistances

R = ohmic resistances (all equal in magnitude) used in the addition circuit.

R_1, R_3, etc. are ohmic resistances defined where used.

Amplifiers and Potentiometers

A_1 through A_9 represent negative feed-back low-output-impedance 400-cycle amplifiers.

θ' = angular position of potentiometer wiper which corresponds to the minimum gain on the voltage divider.

θ''' = angular position of wiper corresponding to unity gain on the voltage divider.

$\theta'' = (\theta'+\theta''')/2$.

α = voltage gain of a voltage divider $(\alpha \leqq 1)$.

β = over-all voltage gain of a voltage divider and an amplifier in cascade.

δ = voltage gain of a three-position voltage divider used in the calibration circuit.

G = voltage gain of an amplifier.

Constants

N_1 = a real number, chosen to be slightly greater than the largest value of b_i. It reduces the gains which would otherwise be required of amplifiers *A1*, *A2*, and *A3*, and permits the maximum gain of *A1* and *A3* to be made equal to unity.

N_{11} = A real number equal to the gain of

amplifier $A7$ in the ith channel. Through the use of this class of constants, problems may be solved on the machine involving a wide range of values for the function $K_i(t'''')$ and, in the process, the $A8$ amplifiers can be made identical to the $A6$ amplifiers if the $A7$ amplifiers are made identical to the $A4$ amplifiers.

No Discussion

Consideration of Requirements and Limitations of Relaying and High-Speed Reclosing on Long and Heavily-Loaded Transmission Lines

C. E. PARKS
MEMBER AIEE

W. R. BROWNLEE
MEMBER AIEE

Synopsis: Present-day large interconnected power systems have many problems in common with regard to economical line loading, optimum placement of generating capacity, and satisfactory solution of protective relaying and line-reclosing requirements to provide the best over-all system performance. This paper suggests some of the engineering considerations which necessarily must be given incident to the planning and specification of the protective relaying and high-speed reclosing to be applied to transmission lines of considerable length which may serve as stabilizing ties between generating stations of an extensive system. For purposes of discussion, a hypothetical transmission system is analyzed. Companion papers[1,2] deal with the problems in the selection of relaying of the short and medium-length transmission lines of the same typical system.

ECONOMIES in generating costs have dictated the location of generating plants. These chosen locations are, in many cases, remote from the points of large load concentrations. This fact has led to close study of the economics of transmission and invariably included in these studies is the subject of adequate relaying facilities to be applied which will best satisfy the increasingly stringent line-loading requirements. It is well recognized that there is a continuing trend toward higher normal and emergency loading of transmission lines in order to take full advantage of their capability.[3] Higher standards of service at reasonable investment costs necessitate the consideration of a minimum number of transmission paths between load and generating areas. This dictates the operation of lines under short-time emergency loadings up to twice normal. These lines also must operate satisfactorily for very short intervals following system faults at even higher load or swing currents until normal system operation is restored.

Consideration must be given to equipment and methods to develop the full emergency (swing) capability of the transmission system. In the past, system separations have been attributed to out-of-step or simultaneous fault conditions when actually such conditions may not have been present or else could have been prevented easily by proper study and application of adequate protective relay systems. Use of the automatic oscillograph has done much to disprove complicated theories with regard to unexplainable system operations, making it evident that further study of the problem would have produced solutions.

System Studied

The purpose of this paper is to outline the relaying requirements of the two 70-mile 138-kv lines connecting station A, a base load economical generating plant, with a net load interconnected area, substations H and J, see Figure 1.

The two 70-mile transmission lines under discussion are required to serve primarily as the major power supply to the load areas at stations H and J. The generating capability of the local station D is assumed to be limited by lack of available cooling water, and the generating cost differential between stations A and D justifies substantial transmission of power to the load area near station D from station A in spite of rather heavy transmission line losses. Maintenance outages at station D may require heavier transmission line loading for periods totaling perhaps three months of the year than would be economical for year-round operation. A typical resultant heavy loading condition may be taken as 90 to 95 megawatts for each of the two 70-mile lines. While lines of this length are not ordinarily considered as long lines, the heavy concentration of generating capacity at each terminal and the high normal line loading result in relaying characteristics of the long line variety.

Relaying Requirements

Relaying requirements for phase-to-ground faults on the two lines are not too severe. The 138-kv transformer bank neutrals are solidly grounded at each terminal station of the lines, thus providing adequate zero sequence currents under practically any system operating condition. The mutual coupling between the lines must receive close scrutiny, however, to ascertain that positive and selective operation occurs for ground faults at any point on the lines near stations H and J, particular attention being paid to the back-up ground relays on the line between stations H and J.

Phase-relaying requirements are more complex and the solution to proper application in this regard must receive care-

Paper 50-16, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 5, 1949; made available for printing November 22, 1949.

Figure 1. Typical transmission system

ful consideration, realizing that some compromises must be tolerated to meet the conflicting system operating requirements. The conditions which are to be met are summarized as follows:

1. Positive and complete fault protection for all generating and system operating conditions.

2. Adequate allowance for conditions presented by fault-arc impedance.

3. Some measure of backup protection, should the proper circuit breaker fail to operate on fault.

4. Operating reliability with approximately double normal load plus the addition of current caused by system oscillations.

5. Characteristics suitable for high-speed simultaneous tripping and reclosing.

It is of further importance to recognize that certain combinations of circumstances may cause actual out-of-step conditions to exist between systems across one or both of the 70-mile lines. In this case, it is imperative that the two systems be separated on the first complete swing in order to prevent serious disruption of the power system. This consideration obviates the use of any time-delay impedance sequence interlocking arrangement applied to prevent out-of-step tripping on swing currents.

Figure 3. Impedance presented to relays at *AR*, circuit *H* following successful reclosing of lines *AR-H* and *AL-J*

Figure 4. Variation of impedance at relays with external fault cleared sequentially

Network Analyzer Study

In order to provide information on phase relaying for the hypothetical system under consideration, an a-c network analyzer study was made, based on 3-phase faults with 1-cycle relaying and 5-cycle circuit breaker tripping. Three-phase faults only were studied for simplicity. These are only slightly more severe to the over-all system than those involving two phases and ground, which are reasonably common.

Figure 2 shows the impedance presented to the phase relays at station *A* on

Figure 5. Carrier relay protection for circuit *AR-H*

the line to station H for a fault at station A on the line to station J, this fault being cleared at both ends in six cycles, reclosed in 20 cycles and retripped in six cycles. Swing curves taken for the system under this condition indicate that system itself is stable. For comparison, the characteristics of impedance, reactance, and modified impedance distance relays are illustrated with conventional settings of zone 1 and zone 2 tripping (zone 3 not shown). The reactance units require a voltage restrained directional starting unit, and the plain impedance elements require a directional unit.

Figure 3 shows the impedance presented to the phase relays at station A with a fault on the double-circuit line at station A. This diagram indicates that successful reclosure of both lines will prevent system instability; however, if only one line recloses successfully and the other recloses on a fault, the system will become unstable and will separate on the line which reclosed successfully. Successful reclosing of the lines following a transient fault requires that the phase relays should not trip on the resulting swing currents. For comparison, zones 1 and 2 settings of another form of modified impedance relay (with directional unit) are shown, indicating that the swing current is within the zone 2 setting for at least one-half second.

Figure 4 applies to a system other than the one under study, but will illustrate the nature of swings presented to the phase relays on a single-line transmission system joining two areas when a fault occurs on an external line of one of them, the fault being cleared rapidly at the near end and by zone 2 timing at the far end. For comparison a smooth line is plotted, based on treating the areas as a 2-machine problem. Variations about this simplified line are due to swings of individual generating stations of the area in which the fault occurred. The significance of this effect is that whereas the transient stability limitations of a tie line are properly evaluated on an approximate 2-machine basis, the relays on such a tie line must remain inoperative for impedances corresponding to as much as 30 apparent electrical degrees greater than the 2-machine stability limit.

Solution to Relaying Installations

Two possible solutions may be considered for the 70-mile problem under consideration. One of these might be a carrier-pilot scheme using a modified impedance or mho element, shown in Figure 5. In this scheme, a long time backup distance element (omitted for simplification) is in operation at all times, but zone 1 distance relay tripping (not shown) is normally cut out of service by the carrier control switch. The displaced circles operate to stop carrier, set up the tripping circuit, and also to control zone 2 timing, and the larger impedance circles start carrier. However, the presence of a carrier signal cuts out zone 2 tripping. Thus, for normal operation, all line faults are cleared by carrier relays but it is necessary for the swing current impedance to enter the zone of both circles (near and far terminals) to cause tripping where the backup element is set for a long enough time to avoid tripping on swings.

When carrier-pilot protection is to be added to a line already equipped with distance relays, the use of the phase-comparison type of carrier relaying may have advantages, since this type of carrier protection is immune to swing currents. Under this scheme, it would become necessary to provide for tripping on actual out-of-step conditions using a modified setting of the distance relay elements. The reach of the zone 1 elements of the distance relays may be shortened so as to just overlap, thus insuring that at least one end of the line will trip on actual out-of-step conditions, but minimizing the likelihood of undesired tripping. It would become necessary to make zone 2

tripping nonautomatic for normal operation and to set zone 3 timing long enough to prevent tripping on system swings. Application of the phase-comparison type of relaying would have to be closely studied to determine the sequence quantities which would be employed for fault detection. Due to the heavy load currents, both normal and abnormal, which flow on the two lines involved, the relay applied must be able to discriminate correctly between normal and fault conditions. If such a relay is completely desensitized for load currents, faults beginning as 3-phase line faults would not be correctly cleared.

Each of the foregoing schemes have serious limitations and represent severe compromises, especially in back-up protection.

Circuit Breaker Reclosing

It has been assumed throughout this discussion that high-speed reclosing would be applied on the two tie lines under consideration. This of course requires that carrier-pilot relaying of some form would be installed to obtain simultaneous fault clearing at each terminal of the lines. Generating conditions on the two portions of the system being studied further require that the resynchronizing of the two systems must be accomplished very rapidly if serious load-generation unbalance difficulties are to be avoided in the vicinity of stations *D* and *J*.

The most simple and inexpensive form of high-speed reclosing would be of the 3-pole type.[4] However, the serious stability problems that present themselves under any type of fault on one or both lines, whether complete successful 3-pole reclosure is accomplished or not, leads to the conclusion that serious consideration should be given the application of selective or single-pole tripping and reclosing.[5,6] In case of transient faults involving only one phase and ground, only the faulted phase would be tripped at time of trouble and reclosed at high speed. This would usually result in the maintenance of some tie between the two systems, even with certain phases of both circuits being open at the time of a fault. The phases which remain as ties between the two systems would carry synchronizing and some load current, thus retarding the angular drift between the systems during the dead time the faulted phases are being restored to service by high-speed reclosing action. Determination of the type of reclosing to be employed will depend on further stability analyses and on the relative number of single phase-to-ground and multiphase faults expected, both for single-line and double-circuit faults.

Conclusions

Certain salient points which may govern or determine the selection of relaying and reclosing applied to a hypothetical system have been discussed. It is realized that each power system will require individual study for the selection of the appropriate protective scheme. However, it is believed that a large number of power systems will contain transmission links of the type to which the following conclusions may well apply:

1. Modern transmission line-loading practices require relaying systems with greatly improved discrimination in order to: withstand heavy emergency loads and swing current without unnecessary trip-outs; provide positive fault protection with allowance for arc impedance; withstand swings inherent with high-speed reclosing; and provide at least some measure of backup protection.

2. High-speed reclosing of important tie lines should receive favorable consideration. Either 3-pole or single-pole reclosing may be applied, depending on the system stability characteristics and on the number of single phase-to-ground and multiphase faults. Either type of reclosing imposes severe requirements on transmission line relaying.

3. Distance relay elements with modified impedance characteristics provide reduced susceptibility to swing current, but usually are not sufficient for the more severe applications.

4. Time-impedance sequence blocking is seldom applicable to the longer tie lines, since system reliability requires that an actual out-of-step condition be cleared on the first swing.

5. Carrier relaying based on modified impedance relay elements can minimize the possibility of undesired tripping, provided the first and second zone distance relay backup elements are normally out of service.

6. Relaying schemes which minimize the possibility of incorrect tripping involve severe compromise with backup protection, especially the protection against the rare failure of a circuit breaker to trip. Further investigation of methods of backup protection is indicated.

Discussion

R. H. Macpherson (General Electric Company, Philadelphia, Pa.): The authors have described a unique system for obtaining power-swing blocking and out-of-step tripping which is particularly applicable to long lines which serve as ties between parts of a system. Relay characteristics are such that blocking during swings is effected by means of carrier from the remote terminal making it necessary for the swing impedance to enter the carrier-stop characteristics of both terminals before tripping can occur. The second-zone distance trip is also carrier blocked to prevent tripping if the swing impedance stays within the second-zone characteristic for the duration of the second-zone time. The scheme is designed to cause the system to be separated on an out-of-step condition at the section through which the power-swing impedance locus passes. There are systems where it is desirable to cause separation to occur at other than the power-swing impedance locus section in order to keep particular loads with particular generation sources. For such cases the equipment described by W. C. Morris[1] has particular application. Figure 1 of the discussion indicates that the relay would be located at the desired point of separation and all other terminals would be blocked on out-of-step conditions by a conventional time-delay impedance sequence arrangement. The characteristics of the authors' arrangement also are shown for the purpose of comparison.

If the line in question is of lesser importance so as not to warrant the special out-of-step tripping protection or carrier, then straight 3-zone distance relaying could be used.

For very long and heavily-loaded lines subject to frequent swings where carrier is used for functions other than relaying, the additional use of carrier for the power-swing blocking function may be somewhat inconvenient since the reach of the im-

pedance carrier-starting characteristic must be great. The use of the conventional time-delay impedance sequence arrangement for out-of-step blocking and reversed third zone for the carrier-start function would make for fewer interruptions to those carrier functions other than relaying, since the reversed third-zone impedance area can be made small compared to the area of the impedance characteristic described by the authors. See the dashed characteristic of Figure 1 of the discussion for reversed third-zone area, which provides backup protection for faults occurring in the reverse direction.

1. ONE SLIP CYCLE OUT-OF-STEP RELAY EQUIPMENT, W. C. Morris. *AIEE Transactions*, volume 68, part II, 1949, pages 1246–48.

P. A. Jeanne (Bell Telephone Laboratories, Inc., New York, N. Y.): We, in the inductive co-ordination field, are somewhat concerned regarding the possibility of increased use of single-phase switching. There has been much benefit, of course, from the inductive co-ordination standpoint in the improved speed of clearance of transmission-line faults in recent years, and it is hoped that these advantages may not be offset by single-phase switching procedures which might increase materially the duration of induction. The induction I have in mind is that resulting from the unbalanced load currents that might flow during the period one phase conductor is open on a power system which is grounded at two or more points. While the induction under such conditions would usually be much less than under the fault condition, it might result in serious communication disturbance due to both low frequency and noise induction if it persisted for a considerable period such as might be the case if a fault did not clear on the first reclosure and the other two phases were not tripped out. I feel sure that most relay engineers will appreciate the importance of this matter and will take it into consideration in their power-system protection planning.

Cort Lowerison (Southern California Edison Company, Los Angeles, Calif.): The paper by Mr. Parks and Mr. Brownlee has been read by several people in our company who are interested in the solution to problems of this nature.

We wish to compliment the author on their skill in reducing a highly technical subject into a thoroughly interesting and readable paper, even for those of us who are not immediately confronted by such a problem.

We have had very little experience with the type of carrier-current relaying described and no experience at all with automatic high-speed reclosing. Therefore, we do not feel that we are in a position to discuss these phases of the subject. The paper indicates that the problem has been very thoroughly investigated, and everything has been done in so far as is possible with protective relaying equipment.

The subject of high-speed reclosing, however, is worthy of considerable discussion. We realize that the trend of modern engineering is in that direction. The development of very high-speed relaying equipment and modern high-speed oil circuit breakers has made reclosing possible. Whether it should or should not be applied should always remain a separate decision for each special case.

Figure 1. Impedance characteristics of one terminal of a power-swing blocking and out-of-step tripping relay scheme, a 1-slip-cycle out-of-step relay and reversed third zone

The paper will serve as an excellent guide in those cases where the economics of the problem dictate the use of this type of equipment. We realize that the paper is being presented as the solution to a hypothetical problem; however, it is difficult to refrain from suggesting that in real practice it would not be a completely satisfactory solution from our point of view.

The values of load and generating capacity shown in Figure 1 of the paper make it difficult for us to appreciate why a third line or an intermediate switching station would not be economically feasible.

W. A. Morgan (Bureau of Reclamation, Denver, Colo.): The Bureau of Reclamation has had in operation for three years an installation of mho-carrier relaying on two 140-mile 161-kv lines between Parker Dam and Phoenix in Arizona. This installation is one of the most critical that may be found either from the standpoint of length of lines or heavy loading, because of the low magnitude of the fault currents. The comments in this discussion are made with this background.

It is interesting to note that one of the relaying requirements in the paper under discussion is that the two systems be separated on the first complete power swing. This obviates the use of any time-delay impedance sequence interlocking arrangement applied to prevent out-of-step tripping on swing currents. The Bureau came to this same conclusion as described in reference 1 of this discussion. This reference paper has impedance characteristic diagrams for fault conditions quite similar to those presented in the authors' paper.

In subsequent specifications, the Bureau has taken care of the out-of-step tripping requirement in a manner such as to provide better backup protection. The need for backup protection was demonstrated by the staged fault test described in reference 1. The out-of-step blocking relays are specified to accomplish the following:

1. Provide backup protection for the zone 2 units of the distance relays.
2. Block tripping by carrier and by the first- and second-zone elements for out-of-step conditions.
3. Block high-speed reclosing after out-of-step tripping.
4. Permit tripping for line faults occurring after out-of-step blocking is initiated but prevent reclosing after such tripping.

These requirements of the out-of-step blocking relays are offered as an adjunct to the section on Solution to Relaying Installations in the paper by Mr. Parks and Mr. Brownlee in line with the last sentence of that section which states: "Each of the foregoing schemes have serious limitations and represent severe compromises, especially in backup protection."

With regard to single-pole reclosing, I would like to offer the following comments. I believe the complication of relaying and circuit breaker mechanism to accomplish single-pole reclosing makes it a marginal benefit difficult to justify for the following reasons:

Mutual coupling from the unfaulted phases maintains the arc of the faulted phase so that the minimum time for single-pole reclosing must be up to about eight cycles longer than for 3-pole reclosing. This has been established by French engineers, and recently by the Bonneville Power Administration in staged tests. The increased reclosing time required for single-pole reclosing leaves little benefit to be gained for transient stability conditions over the faster 3-pole reclosing where there is more than one line connecting the two systems.

The percentage of single-line-to-ground faults on steel tower transmission lines with overhead ground wires now is found to be closer to 40 per cent by automatic oscillographs, whereas it was thought to be close to 90 per cent when relay targets were used as the basis for data. In the same manner, 3-phase faults are found to represent about 30 per cent instead of 1 to 3 per cent. This is true because the relay-target circuits reduce the current through the remaining unoperated targets after one has operated. The basis for the more accurate percentages of one-line-to-ground and 3-phase faults is reference 2 of this discussion. Theoretical analysis of lightning-stroke phenomenon makes it logical to expect a larger percentage of 3-phase faults on steel tower lines with overhead ground wires than we previously designed for on rules of thumb based upon relay-target data. Accordingly, single-pole reclosing would be expected to operate for only about 40 per cent of lightning faults.

The use of a blinder relay element[1] would allow fast backup protection and avoid tripping on swings. This might overcome the point of weakness in Conclusion 3 of the paper. There is some objection to the use of a blinder relay element, however, in that it adds another gadget to the relaying which it is usually desirable to avoid.

It may be of interest to report to the credit of the mho-carrier relays, including the blinder elements, that the phase relays have operated correctly to prevent tripping on the unfaulted line during these three years of operation. During this time there have been four faults that have occurred on the two Parker-Phoenix 161-kv lines at different

times, after the modifications, as described in the Morgan and Evans paper,[1] were made. The modification of the carrier ground relay to prevent tripping on line-charging harmonic currents allowed false tripping in one instance of a ground fault outside the protected zone, however, and the relays are undergoing a change in connections, which it now appears will correct the error in the directional characteristic.

I believe that the value of a paper may be brought out by a healthy discussion both pro and con. Thus, I trust that the authors appreciate that my comments are offered for the purpose of stimulating thought in a subject in which I am greatly interested.

C. E. Parks and W. R. Brownlee: The amount of agreement expressed by the various discussers is most gratifying, especially in view of the recognized compromises which have been made between the conflicting relaying requirements imposed by the hypothetical power system

Mr. McPherson describes an alternative scheme in which a conventional time-delay impedance sequence arrangement is used to block tripping. The indicated use of the 1-slip-cycle relay does much to remove objections to earlier blocking schemes in which separation of out-of-step portions of the system was delayed. Where important loads are supplied from a major tie line, the preselection of the point of separation may be of value. However, it is important to provide rapid emergency separation (on the first swing) at some point on each major transmission linkage across which an out-of-step condition may occur.

We agree with Mr. McPherson that there is a definite field for distance relays on lines for which the more expensive carrier-current relaying cannot be justified.

Mr. Jeanne very properly places a high valuation on the co-operative work of communication company and power company engineers in the economic solution of inductive influence problems. The single-pole reclosing system with which the authors are familiar is associated with high-speed carrier-current relaying, so that the total time of fault current plus phase-to-neutral load current is of the same order as the total fault time with more common types of relaying systems. Also, if instantaneous reclosing is unsuccessful, all three poles of the circuit breakers are tripped together. The authors know of no scheme in the United States in which it is proposed to operate a high-voltage transmission line for longer than a fraction of a second with one pole of the circuit breaker open and the other two closed. Such a scheme might involve severe inductive influence problems.

The tests reported by Mr. Morgan have indicated that single-pole reclosing may require some eight cycles longer open time than 3-pole reclosing because of the mutual coupling from the unfaulted phases. On many 138-kv systems, the usual 3-pole reclosing time is about 20 cycles and the corresponding single-pole reclosing time some 35 cycles. Accordingly, it is not surprising that the limitations described by the discusser have not been encountered.

Individual study will determine the relative applicability of single-pole and 3-pole reclosing in specific instances. In the case of lines having only 40 per cent of single-phase-to-ground faults, the use of single-pole reclosing would be of limited value. However, it must not be inferred that the relatively high percentage of single-phase-to-ground faults (70 to 90 per cent) found on many 138-kv lines is based on relay targets. On the contrary, oscillographic records covering periods of over 20 years have established these ratios.

Mr. Lowerison questions whether a third 138-kv line is justifiable on an economic basis, recognizing that the hypothetical system described was chosen to illustrate certain relaying problems. The heavy loading which sets the relaying requirements may occur for only a short period each year, during times when a generator at Station *D* is out of service for maintenance. See Figure 1 of the paper. Accordingly, it might be difficult to justify a third line from Station *A* to the west on a loss evaluation basis. The possible justification of a third line from the standpoint of service reliability to Area *D-H-J* will depend on the probability of outages on Lines *A-H* and *A-J*, and especially on the probability of a 2-circuit outage along with a sustained fault on one of the lines. Regardless of the appropriate factors applied to any particular situation, it appears certain that improved relaying and reclosing schemes will make it possible to provide for adequate service at relatively lower transmission system investment.

Margins Between Lightning Arrester Protective Levels and Transformer Insulation

F. J. VOGEL
FELLOW AIEE

CURVES showing the relations between lightning arrester discharge voltages and transformer impulse strength are often published, to show the margin between the two and to illustrate how securely protection is obtained. As published, they always show a considerable margin, and further, they reflect the values set up as commercial standards.

Some engineers, particularly transformer engineers, are interested in the conditions possible in service to see if the apparatus they design is adequate for service.

Some operators, too, are interested, since they buy both lightning arresters and transformers, and the establishment of "basic insulation levels" depends on these relations.

Impulse tests have been made by transformer engineers in the past, using lightning arresters and transformers, for this purpose, but the results were never published. One such test is reported here, which does not conform to the usual impression of the relations between lightning arresters and transformers, but does indicate that a high degree of protection is obtained.

General

The standards of lightning arrester performance have recently been presented.[1] They are extremely valuable in standardizing the method by which lightning arresters can be tested to determine compliance with commercial standards and to give an idea as to the limiting voltages under these conditions.

Using such data, curves showing the degree of protection to apparatus can be drawn. The curves shown in Figure 1 are illustrative of the relations usually given, to show the minimum values of transformer insulation and the average lightning arrester performance. However, there are some other considerations to be taken care of to obtain the real picture. One of these is the fact that the lightning arrester performance is average and may exceed the values shown by 10 or 15 per cent. Actually, it is very likely that this is a pessimistic viewpoint. But there are some matters which make conditions worse. Such conditions are separation of the lightning arrester from the apparatus, and the possibility of high rates-of-current discharge, or high rates-of-rise of such discharges.

One method of allowing for them has been a fixed percentage, or a fixed quantity, or both. However, to the writer's belief, little experimental data as to the correspondence of this allowance and possible actual field conditions have been presented. Experience showing that the use of the allowance has given good service has been given as justification.

The transformer standards establish minimum values of transformer insulation. These values are exceeded for two reasons: first, there must be some margin allowed for testing. For example, if a chopped wave of 230 kv is required, the tester calibrates the surge generator at some lower voltage and determines the charging voltage for 230 kv by extrapolation. Depending on a number of variables, the actual voltage and specified time may be exceeded by 10 to 15 kv or one or more microseconds. Second, the designer will attempt to provide a margin to prevent failures on test and damage. On the other hand, the conditions used for test on the lightning arresters are not as severe as they might be, since a 10/20 current wave is the basis of test. Hence the commercial tests do not put the transformer in a particularly favorable light, and, on the contrary, they put the lightning arrester in a favorable one. A more logical method of procedure would be to use minimum strengths for the transformers, as is now done, and maximum (not average) which limiting voltages for lightning arresters should be at least one of the test or guarantee values. Perhaps also they should include the most severe current condition to be expected in service.

In order to illustrate this point of view, some tests were recently made on some 34.5-kv transformer coils and insulation, both with and without lightning arresters. The point was to illustrate the effect of steep rates-of-current rise and separation of the lightning arrester from the transformer. The tests are not beyond question so far as some technicalities are concerned, but they certainly are illustrative of possible field conditions.

Test Procedure and Results

The coils and insulation used were typical for 34.5-kv class, which should stand the following tests: full wave, 200 kv; chopped wave, 230 kv; steep-front wave, 345 kv in 0.5 microsecond.

The transformer coils and bushing were set up with a 9-inch rod gap as near as possible. The surge generator was adjusted to give a rate-of-voltage rise of

Paper 50-17, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 28, 1949; made available for printing November 22, 1949.

F. J. Vogel is with the Illinois Institute of Technology, Chicago, Ill.

The data presented in this paper were obtained during the development of a possible new line of transformers at the Pittsburgh works of the Allis-Chalmers Manufacturing Company.

Figure 1. Relations between lightning arrester performance and test data

Average data for 37-kv-line-type lightning arrester shown on dash line. Curve is estimated but is assumed for 10/20 current wave to give a $1^1/_2/40$ voltage wave.

Solid line represents minimum values for transformers demonstrated by test.

Crosses (x) represent voltages at lightning arrester and transformer, with both as near together as possible. The crest of the wave was at less than one-half microsecond, and the average value was over 220 kv for the equivalent, approximately, of at least 3 microseconds, Figure 3(B). It is recognized that these do not form points on a time lag curve, but show comparative strengths only.

Circled crosses represent the lightning arrester and transformer voltages with 50 feet separation. The 326 kv at the transformer had very short duration, shown as less than one-half microsecond, Figure 3(E). The lightning arrester voltage is shown as 235 kv for the equivalent of 3 microseconds, Figure 3(F).

This comparison shows how the separation between the lightning arrester and transformer, leading to high frequency oscillations, requires steep wave front strength

about 1,500-kv per microsecond. The result of the test is shown in Figure 2(A). The voltage was 513 kv, reached in about 0.33 microsecond.

Next a 37-kv lightning arrester, of good manufacture and rated as a line-type arrester, was set up as close as possible to the transformer model. It will be noted that the voltage is greatly reduced as shown in Figure 2(B), to be a relatively long wave but to be only 176 kv.

Further tests were made with the lightning arrester between the transformer and generator. The generator setting was unchanged. On one such test, the voltage at the lightning arrester is shown in Figure 2(D), and was 176 kv. The voltage at the transformer was shown in Figure 2(E). The peak was 214 kv.

The distance between the lightning arrester and the transformer was 50 feet of line. It would seem that this might be a possible condition in the field. Although the voltage at the transformer was 214 kv, it existed for a small fraction of a microsecond.

Since voltage rises of lightning of 1,000 kv per microsecond have been cited, this might be considered to prove that, at least so far as ordinary rates-of-voltage rise are concerned, the lightning arrester has done a very good job, preventing flashover and limiting the voltage on the apparatus. In these tests about 500 ohms of resistance were in series within the generator.

Another series of tests were made without internal resistance in the generator. The model and 9-inch rod gap were close together. Figure 3(A) shows a flashover on the front of the wave of 556 kv, reached in one-fourth microsecond, giving a rate-of-rise of over 2,200 kv per microsecond. With the lightning arrester immediately adjacent, the maximum voltage was 262 kv and the average of the curve was 220 kv. It decreased rapidly in a microsecond or so. This is shown in Figure 3(B).

Similar tests were made with various separations between the lightning arrester and transformer. One such test was made with 25 feet separation. In that case the voltage at the lightning arrester was 246 kv and is shown in Figure 3(D). The voltage at the transformer was 310 kv and is shown in Figure 3(C).

It is easy to see that the duration of this voltage is only a fraction of a microsecond.

Results with 50 feet separation are shown in Figures 3(F) and (E), where voltages at the lightning arrester and transformer are shown in respective order. The highest voltages were 235 and 326 kv respectively. The 9-inch gap was in parallel with the transformer for all tests.

There were no gap flashovers during the tests described.

After these tests and many even more severe, investigation showed that no damage was done to the transformer insulation.

No measurements of discharge currents were taken, to simplify the tests. Such measurements would be desirable by those interested primarily in lightning arrester performance.

Discussion of Test Results

Although these tests make no pretense of being a complete study of the subject,

Figure 2. Oscillograms with 1,500 kv per microsecond wave

(B) Lightning arrester voltage, same surge generator setting as (A)

(C) Transformer voltage 50 feet from lightning arrester

(D) Lightning arrester voltage corresponding to (C)

it is believed that they do permit drawing some conclusions, some not new.

For example, the conditions illustrated here, even in the worst case, are probably not as severe as they could be in service. Under these conditions, protection was actually obtained both to service and the apparatus with the lightning arrester. Protection to the apparatus was obtained only with gaps. The limits of assumed lightning severity perhaps should be further explored, since no general agreement as to lightning arrester current limits for given voltage classes and applications has been reached. Since the effect of separation of the lightning arrester and apparatus results in short steep-front oscillations, it would seem that steep-front strength in transformers is desirable. Unless conditions much worse than in these tests exist, normal transformer levels would seem to be sufficient. In other words, high-voltage oscillations due to reflections are not too greatly to be feared if steep-front strength is built into the apparatus.

The relatively longer steady voltage durations, with high lightning arrester currents, and with the arrester at the transformer, seem to be close to or exceed the present transformer levels. Actually they did not exceed the strength as actually built in, even in the worst case. If the transformer barely had the American Standards Association level of full wave strength, more failures might result in service. The usual relations shown for lightning arresters and transformers do not seem entirely correct. They are indicated in Figure 1. However, I do not believe margins should be added on to other margins. Present levels seem satisfactory to me.

The relations here given apply to the lower voltage classes. Conditions might be much different for higher voltage classes. Tests under these conditions have been made before, and it might be well if more comprehensive tests were made and reported. Due to overhead ground protection, surge currents are often small, and if so, transformer insulation might even be reduced.

Discussion

E. C. Starr (Oregon State College, Corvallis, Oreg.): The information presented in this paper, together with that in the paper by Mr. Rorden,[1] will be of great value to engineers whose duty it is to design the insulation protective systems of high-voltage substation equipment. The performance of lightning arresters subjected to steep-front voltage and current waves has not previously been made available, generally, to utility engineers, and a seemingly unnecessarily large margin between lightning arrestor block voltage and transformer-withstand capacity has been recommended.

Mr. Vogel's oscillograms point out the necessity for a substantial margin, but they also indicate that for travelling-wave discharge duty, the lightning arrester momentary initial overvoltage, together with the overvoltage occasioned by modest lead lengths between the lightning arrester and transformer, is of such short duration as to fall within the short-time high-strength region of modern transformer insulation, and therefore not materially to reduce the margin indicated by the standard 10 by 20-microsecond current-wave tests on lightning arresters. For station-type lightning arresters located in close proximity to the protected equipment, that is of the order of 50 feet or less, it seems that a margin of 25 or 30 per cent between the average block voltage of the lightning arrester at 5,000 amperes and the transformer withstand value should be adequate when the station is so protected that surges of a traveling-wave character only, limited by line and station insulation flashover, are permitted to impinge upon the apparatus. The lightning arrester block voltage referred to is that obtained in the standard 10 by 20-microsecond current-wave test, and the transformer withstand value is that indicated by the 1.5 by 40-microsecond full-wave surge test.

The design factors now are rather clearly indicated.

Reference

1. Lightning Arresters as a Criterion for Insulation Levels, Harold L. Rorden. *AIEE Transactions*, volume 69, part I, 1950, pages 84–96.

P. L. Bellaschi (Consulting Engineer, Portland, Oreg.): In view of the renewed activities in rationalizing of basic insulation levels, the contribution by Mr. Vogel is pertinent in that it draws attention once again to some of the problems of protection

and co-ordination of station insulation. One of the factors to consider in the protection of station equipment is the lead effect between the protective device and the apparatus protected. Leads and busses of the usual lengths encountered in stations can well be represented by a lumped inductance (L_1) and for the short time involved the transformer in effect is a capacitance (C_T). A 60-foot bus corresponds to about 20 microhenries and a large power transformer in the order of 1,500 to 2,000 micromicrofarads. The problem is conducive to calculation. For an incoming surge on the line, appearing at the lightning arrester rising to lightning arrester crest voltage E in one microsecond and limited to that voltage by the lightning arrester, the surge voltage e_T at the transformer is

$L_1 = 20$ microhenries

$C_T = 2{,}000$ micromicrofarads

$$e_T = \left(t - 0.2 \sin \frac{2\pi}{1.26} t\right) E, \text{ for } 0 < t < 1 \text{ microsecond}$$

$$e_T = \left(1 + 0.192 \cos \frac{2\pi}{1.26} t - 0.145 \sin \frac{2\pi}{1.26} t\right) E, \text{ for } t > 1 \text{ microsecond}$$

Thus for an incoming surge rising to lightning arrester crest voltage E in 1 microsecond and maintained to that voltage at the lightning arrester, a 60-foot bus between lightning arrester and transformer and terminating at the transformer, the surge voltage at the transformer (e_T) is the lightning arrester voltage (e_A) plus a superimposed oscillation 24 per cent above the lightning arrester crest voltage (E), of a period $T = 1.26$ microseconds and decaying after several oscillations down to practically zero. For a 120-foot bus, the overvoltage attained would be 55 per cent above lightning arrester crest voltage, of a somewhat longer duration (period) because of the higher lead inductance.

The overvoltage at the transformer depends on the ratio of the duration of the front to the period of oscillation of lead (bus) inductance and transformer capacitance. The dissipative characteristics of lightning arrester, leads and other circuit elements naturally reduce the overvoltage developed. Another factor in the protection problem at the shorter times is due to an inherent "delayed ionization effect" in the lightning arrester proper when subject to rapid surge current discharges. This effect can accentuate the over-voltage at short times by an appreciable amount. The oscillations of the voltage appearing at the transformer shown in Mr. Vogel's paper are of the character indicated in the foregoing analysis. It would have given greater significance to the results presented in the paper had the author recorded the corresponding surge currents through the arrester.

Because of their inherent strength to the shorter impulses, transformers designed and tested in accord to current standards are well capable of withstanding voltages of the character indicated in this discussion and in the paper. A certain length of lead or bus between lightning arrester and transformer is permissible, the amount depending on the rate of rise of voltage at the lightning arrester, the surge current discharged (rate of rise and magnitude) through the lightning arrester, protective characteristics of the lightning arrester, volt-time characteristics of the transformer and its basic insulation level.

Present-day knowledge of lead effect, lightning arresters, and station apparatus is reasonably comprehensive and quantitative. It has been applied effectively to station design. For example, to quote briefly from Report 317 of the International Conference on High-Voltage Electric Systems[1] presented in 1939:

"It is apparent that for effective protection and co-ordination of station apparatus against very steep impulses, consideration must be given to the circuit feet of leads connecting the various station parts and to the proper location of the protective devices. The most effective method is to mount the lightning arresters on the transformers. Conditions in the station layout or due to the apparatus may not always permit this arrangement. In such cases, the lead voltage can be minimized by locating the lightning arrester as close as possible to the transformer or apparatus it is intended to protect. A protector tube or suitable rod gap located at the line end of the station, will afford additional protection to the station apparatus against steep-wave-front impulses that may enter the station. The problems arising in protecting a large station against very steep voltages can be overcome by increasing the effectiveness of the overhead ground wire and the grounding (counterpoise) to the extent that the only possible voltages entering the station would be in effect impulse voltages of duration greater than 2 or 3 microseconds. It should be recognized that the presence of multiple lines, as well as the station capacitance, contribute beneficially and in no small measure to protection."

During the past 15 years many impulse tests have been conducted in the various laboratories on transformers in combination with lightning arresters as well as other protective devices, and the findings in large part have been incorporated in station insulation design. The lead and other short-time effects in relation to the strength of station insulation at the short- and long-impulse times and to the over-all problem of protection and co-ordination have been recognized and taken into account, in certain quarters at least. However, it is well that attention is called to these problems and re-examined.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The paper touches on a subject of present importance because of the work that is being done on insulation co-ordination by the Triple Joint Committee. In the tests involving lightning arresters, it is regretable that records of the discharge currents were not made to correlate with the voltages recorded at the lightning arresters. As indicated in the paper, co-ordination demands that some conclusions must be reached on the lightning arrester discharge current which is to be used as a basis for determining a protected level maintained by the lightning arresters. In my opinion the performance data for lightning arresters should be chosen so that the voltage which appears across lightning arresters co-ordinates with the type of voltage on which transformer withstand strengths are based, for it does not seem logical to me to compare two sets of data of different nature. It should be noted that the lightning arrester used by Mr. Vogel was a line-type lightning arrester. In the discussion of basic insulation levels and so forth, it seems to me that the protective level on which the basic insulation levels are based, should be that afforded by station lightning arresters if full advantage is to be taken of available levels.

Although Mr. Vogel's paper contains no information on the magnitude or wave shape of the lightning arrester discharge current, there appears to be some disagreement between Mr. Vogel's paper and the data presented in Mr. Rorden's paper, as to the performance data, if the ratio is the same as the ratings of the lightning arresters tested by Mr. Vogel and Mr. Rorden. Tests made in our laboratories do not check with some of Mr. Vogel's results.

I am in agreement with Mr. Vogel's suggestion that lightning arrester performance be stated on the basis of the maximum value expected rather than the average, or possibly, subject to further discussion and debate, on some probable value which is higher than the average but lower than the maximum industry value, as has been suggested by the National Electrical Manufacturers Association.

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): In Mr. Vogel's tests there were no measurements made of the lightning arrester discharge currents so no direct comparison can be made with other measurements. The high test currents are very short in duration, about 4 microseconds for the first half cycle. The lightning arrester discharge voltage characteristic is a function of the rate of rise of the discharge current as well as the magnitude of the current. However, the measured lightning arrester discharge voltages in Figure 3 seem to be too high. Also in this figure the shape of the lightning arrester discharge voltage is not normal. Figure 3(A) is the sparkover of the 9-inch air gap. The voltage after sparkover does not fall immediately to zero as it should. The voltage passes through zero and reverses at crest current, 2 microseconds after the beginning of the surge. This excess voltage measured across the 9-inch rod gap can best be explained by inductive drop in the line and ground leads to the gap. The voltage across the gap leads is high, about 100 kv as the trace leaves the edge of Figure 3 (A) and still higher just after gap sparkover.

If such line and ground leads, or parts of the same leads are included in the arrester voltage measurement, Figure 3 (B), the shape of the arrester voltage can be understood. The inductive drop in the lightning arrester leads is directly additive to the discharge voltage. A correction for the voltage drop across the leads would bring the lightning arrester discharge voltage characteristic to the same level as in Figure 2. The lightning arrester characteristics in

Figure 2 are about normal for high rates of rise of current.

Effective protection of transformers under the rapidly rising surge voltages and currents used in these tests, requires that voltage drop due to line and ground leads to the lightning arrester be reduced to the minimum. Mr. Vogel's tests in the laboratory with very moderate length leads showed about 50 per cent overvoltage. In service, the optimum lightning protection would be obtained by mounting the lightning arrester on the transformer tank which can place it directly in parallel with the transformer bushings with a minimum of lead to reduce the effectiveness of the lightning arrester.

F. J. Vogel: I wish to thank Professor Starr for his discussion.

Referring to the mathematical part of Mr. Bellaschi's discussion, it is indeed old. However, the performance of the lightning arrester with steep rates of current rise has not been generally recognized, nor has its performance been compared directly with transformer characteristics publicly. Also, as Mr. Bellaschi stated, combination tests have been made, but to my knowledge, they have not been reported. The purpose of my paper was to call attention to the lower voltage class of transformers, up to 69 kv, where overhead protection from steep front waves might not be economical, and to show that they would be protected with even line-type lightning arresters, against very severe lightning surges.

The discussers generally called attention to the lack of discharge current information. One reason it was not obtained was because a study of lightning arrester performance was not within the scope of the project. It was desired to show that steep front strength of transformer insulation was desirable, that a new design of transformer would be protected against a very severe surge, and that it would give good service in use. The test was made with only one type and make of lightning arrester. Incidentally, it pointed out that the present lightning arrester standards did not tell that higher voltages occurred with steep front waves. Mr. Beck clearly appreciated this point of view, when he said that "co-ordination demands that some conclusions must be reached on the lightning arrester discharge current which is to be used as a basis for determining a protective level maintained by the lightning arresters." Some may claim they do this by using present standards and making allowances for these other effects. However, tests such as mine can be made easily, and if current measurements are necessary could be included. Station-type lightning arresters should not be the sole type studied in my opinion.

I am not much surprised that my data and Mr. Rorden's do not entirely agree. I am sure that the currents and the rates of current rise are much higher in my tests. There was no great length of line between the surge generator and the lightning arrester. Measurements were made as nearly as possible at the transformer.

I was very much interested in Mr. Opsahl's discussion, because in it he brings out a difference in point of view, and because he is technically correct in his reasoning as to Figure 3(A).

The circuits used for both Figures 2(A) and 3(A) were reported to be the same, except that a minimum of resistance and inductance were in the generator circuit for Figure 3(A). Nevertheless, a part of the inductance drop due to current in the main generator circuit is undoubtedly present. Personally, I doubt if it affected the magnitude of the voltage very greatly in the case of Figure 3(A), or for that matter the crest values of the other oscillograms. Other data for the 9-inch gap about checks that for Figure 3(A).

Insofar as the point of view is concerned, I am not so interested in what the lightning arrester does without leads as I am with them.

In Figure 3(B), a minimum of leads was present. The voltage measured was at the transformer. This is the value that interested me. Further, the lightning arrester I used might not have been representative of other lightning arresters made by Mr. Opsahl's company, or it might not even have been made by his company. And finally, the purpose of my paper, to show that some separation between lightning arrester and transformer still gave optimum protection, was entirely misconstrued, since I thought the paper showed that effective protection with line-type lightning arresters was obtained.

I would like to take exception to the lightning arrester standards if the proposal to use an average +2/3 of a possible maximum is adopted. I do not think that it will actually mean much since transformer insulation is not designed within 5 per cent, and this allowance would be in that order. But if some lightning arresters, on test at assembly, might be at the maximum value, I think it would be better to say so, and make provision for a test of a complete lightning arrester, if specially required, to demonstrate it was below this value. People seem to expect transformers to meet the tests, rather than the 5 per cent lower values.

Harmonic Index—A Tool for Transformer Audio Noise Investigation

W. H. MUTSCHLER, JR.

T. F. MADDEN
ASSOCIATE AIEE

Synopsis: The harmonic index is the decibel difference between the noise level obtained with the flat weighting and the noise level obtained with the 40-decibel weighting. It is a qualitative measure of the harmonic content of the noise measured at a given point. The harmonic index was introduced several years ago,[1] but it has not realized the consideration which it merits. It is the purpose of this paper to demonstrate the value of the harmonic index when used in conjunction with the flat weighting measurements as a simple approach to the problem of evaluating the complex structures of the transformer.

TRANSFORMER audio noise is a problem which has confronted both the users and the manufacturers of transformers for many years. The rapid growth of transmission and distribution systems within recent years has necessitated the location of power transformers within residential districts and, at times, within buildings. As a result, power companies employing such installations have become even more noise conscious.

During the same interval a new electric core steel has been developed which operates at a much higher flux density to produce a smaller, more economical transformer. The magnetostrictive effect of these new highly oriented cold rolled steels is less for a given density; however, this advantage is offset by operating at higher densities. In order to utilize the economic advantage of these newer steels and to reduce the transformer noise at the same time, it becomes necessary to eliminate, as completely as possible, the sources of resonance in the transformer structure and to find methods for the attenuation of the noise energy within the transformer.

Means, such as sound absorbing enclosures, for the attenuation of the noise external to the transformer have been developed, but such devices are costly. Since, in most cases, the transformer noise must be decreased because of complaints, either a quieter transformer must be obtained for the location or these costly devices must be employed.

In order to eliminate the source of resonance and to find the attenuating effects of changes made in the transformer structure, it becomes necessary to evolve a simple method for the evaluation of the effects of these changes. The harmonic index and the physical noise level of the transformer are the tools which can be employed for this evaluation.

Magnetostriction

Magnetostriction, the minute dimensional variations in ferro-magnetic materials during magnetization, has long been recognized as the main source of transformer noise.[1,2,3] Magnetostriction is present in electrical sheet steel in the order of several micro inches per inch and varies with flux density as shown in Figure 1(A) for cold rolled steel and in Figure 1(C) for hot rolled steel. Although the magnetostriction in cold rolled steel is less than that of hot rolled steel at the same value of flux density (in Figures 1(A), 1(B) and 1(C) a flux density of 12 kilogausses was used) the higher flux density dictated by the economical operation of cold rolled steel more than offsets the reduction of magnetostriction accomplished by orientation in the steel. In either case, the minute vibrations set up by the alternating flux in the core constitute an appreciable source of sound energy. The predominance of the higher harmonics in cold rolled steel makes the noise generated by it more objectionable than that produced by hot rolled steel.

From the viewpoint of noise generation, cold rolled steel has one further disadvantage—it is sensitive to cold working which may result from rough handling during the manufacturing process. Figure 1(B) shows the effect of mishandling cold rolled steel. Cold working of this steel disturbs the orientation and the magnetostrictive characteristic becomes similar to the magnetostrictive characteristic of hot rolled steel.

In the economical application of these steels, the optimum in noise performance is dictated by the maximum amplitude of magnetostriction, the maximum operating flux density and the physical characteristics of the core. Since magnetostriction is a physical property of the steel, it is difficult to control internally the sound energy which the steel is capable of producing at a given flux density. By increasing the silicon content to approximately $6^1/_4$ per cent, the magnetostriction is reduced to a negligible amount but mechanical requirements prohibit the use of this high value of silicon content.[4,1] In all cases known to date, either mechanical or economical considerations prohibit the manufacture of a "zero-magnetostriction" electrical sheet steel. The only means available to the transformer manufacturer of curbing the noise generated is through the attenuation of the more objectionable frequencies in the noise spectrum.

Mechanical forces due to load currents in the coils will give rise to 120-cycle noise. The magnitude of the noise thus produced is in general sufficiently below the magnitude of the 120-cycle component produced by the core so that it will not contribute to the over-all noise picture.[1,2,3]

Paper 50-18, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, January 30–February 3, 1950. Manuscript submitted November 2, 1949; made available for printing November 29, 1949.

W. H. MUTSCHLER, JR. and T. F. MADDEN are with the Allis-Chalmers Manufacturing Company, Pittsburgh, Pa.

The authors wish to extend their appreciation to J. B. Hodtum for his helpful assistance throughout the preparation of this paper.

Resonance

The secondary source of audio noise in a transformer is resonance of the mechanical structure. Resonance and the extent of its influence on the noise level of a transformer may vary considerably depending upon the number of members in the structure that resonate, the resonant frequency of each member and the magnitude of the driving force of this frequency in the core.

If the vibrational amplitude of a given frequency is doubled by resonance, the noise level will be increased six decibels for this frequency. Resonance is capable of increasing the vibrational amplitude four or five times, which will cause an increase in noise level of 12 or 14 decibels. Fortunately, the distributed characteristic of the transformer noise plus the fact that resonance does not normally exist at more than two or three frequencies prevents the realization of such large increases in noise level; however, resonance may account for increases in noise level up to six decibels, which is often the difference between a noisy transformer and a quiet one.

For core-type transformers, as well as shell-type transformers, it has been found that the resonant frequency of the core can be determined analytically. In the core-type transformer, the resonant frequency is a function of the free length of the leg and the width of the laminations. By proper selection of these dimensions by the design engineer, resonance can be eliminated in the core and thereby the noise of the core can be reduced to a minimum. With the addition of side frames and the winding assembly, some resonance may be introduced into the transformer. What effect these additions will have can best be determined experimentally.

After the core and coil assembly is immersed in oil, the vibrations of the core are reduced by the damping force of the liquid.

This damping force is proportional to the density of the oil and of the frequency of the vibrations. The damping force, therefore, which acts on the higher frequencies is greater than the damping force which acts on the lower frequencies. It can then be expected that, after tanking, the physical noise as well as the harmonic content of the noise will be decreased.

Since the oil is an incompressible fluid, the vibrational amplitudes, decreased by the damping action, are then transmitted to the tank wall. Some of the vibrations are also transmitted to the tank wall by the supports of the core and coil assembly. The damping force of these supports depends upon the method of supporting. In general the damping forces of the supports are small, and the vibrations are transmitted to the tank with little damping.

When the vibrations reach the tank they are either attenuated by the mass and stiffness of the tank walls or accentuated by resonance in the tank structure. The tank surface is broken up into many small areas by radiators and other members which are welded to the tank wall. As a result, the tank will have numerous resonant frequencies and, as in the core and coil assembly, resonance cannot be treated analytically but can be determined experimentally.

Since some frequencies may be attenuated while others are accentuated, the noise spectrum of the transformer after tanking will be somewhat different from the noise spectrum before tanking. The noise spectrum is the distribution of harmonics determined by the harmonic analysis of the noise. Resonance therefore can be determined by obtaining the noise spectrum before tanking and comparing it to the noise spectrum after tanking to locate the frequencies at which resonance occurs.

Harmonic Analysis

The noise spectrum obtained for the core and coil assembly of a transformer to be used as a basis for comparison with the completed transformer is shown in Figure 2. After the transformer is tanked, the noise spectrum is again obtained, Figure 3.

By comparing these spectrums it can be seen that in the example chosen the 600-cycle as well as the 1,080-cycle noise level is higher after tanking which indicates that there is predominant resonance at these two frequencies. Steps were taken to eliminate resonance at these frequencies and the noise spectrum was again determined. Figure 4. Here the 600-cycle and the 1,080-cycle noise levels are reduced to values comparable to those obtained on the core and coil assembly alone. The noise level of the transformer before any changes were made was 55.8 decibels; and, after the changes were made, the noise level was 53.0 decibels. The elimination of resonance in this particular case caused a decrease in noise level of 2.8 decibels.

The noise spectrum provides an excellent method for obtaining the frequencies at which resonance occurs. In order to obtain the noise spectrum, however, numerous readings must be taken and analyzed. Since there are variations in magnetostriction from one lot of steel to the next, the refinements obtained by using the noise spectrum prevent the use of a typical noise spectrum. These two factors combine to make the harmonic

Figure 2. Noise spectrum of the core and coil assembly with 60-cycle excitation

C. Noise level—65.3 decibels
A. Weighted noise level—55.8 decibels

analysis impractical. A practical method of analysis then is one in which the data obtained is not quite so sensitive to variations in magnetostriction and one which requires only a very few readings.

Harmonic Index

The harmonic index, *hi*, is defined as the difference between the noise level measured by the "flat" response and the noise level measured by the 40-decibel response curve.

$$hi = db_{(flat)} - db_{40}$$

Since the noise level measured by the "flat" response is equal to the physical noise present and the noise level measured by the 40-decibel response is equal to the noise as determined by the ear, the harmonic index is actually a measure of the attenuation of the physical noise by the ear. Attenuation of the ear is a function of the frequency at which the noise is generated. This is best exemplified by considering two pure tones, one of 120 cycles and one of 480 cycles, both having a physical noise intensity of 55 decibels. The sensation experienced by the ear for the 120-cycle pure tone is approximately 39 decibels, and the harmonic index for this tone is

$$hi = 55 - 39 = 16db$$

With a pure tone of 480 cycles, the attenuation of the ear is less and the ear would experience a sensation equivalent to 51.5 decibels. The harmonic index for this particular tone is

$$hi = 55 - 51.5 = 3.5db$$

Obviously the energy, as observed by the ear, equivalent to a physical noise level of 55 decibels is less objectionable when generated at 120 cycles than it would be at 480 cycles. The importance of this principle is that it may be used to give an indication of the quality of a complex sound such as is generated in a transformer. Noise having a high harmonic index indicates a predominance of low harmonics while noise having a low harmonic index indicates a predominance of high harmonics. Extreme variations in the harmonic index as exhibited by the pure tones above do not take place in a transformer because of its complex nature; however, the significant factor in the application of the harmonic index is the manner in which it changes.

For a given size transformer core the sound energy will be a function of the harmonic content and the maximum amplitude of the magnetostriction in the steel used. Using the amplitude of each frequency obtained from a harmonic analysis of the magnetostriction versus time characteristic, it is possible to determine the average harmonic index and the physical noise level for the core.

If the core has been designed to avoid resonance, the harmonic index and physical noise level of the transformer should be equal to the calculated values. Factors, such as damping pressure, core impregnation, size, and weight of side frames and the windings may influence the noise level of the core. Here the harmonic index can be used to study the effects of each of these factors. If the physical noise level is increased above the calculated value, the range of resonant frequencies can be determined. Thus it is possible to determine what structural changes can be made in the core assembly for maximum noise attenuation.

Table I. Variation of Physical Noise Level and Harmonic Index Between Untanked Transformer and Tanked Transformer

	Variation of		Cause of Variation		
Item	Physical Noise	Harmonic Index	High-Frequency Resonance	Low-Frequency Resonance	Poor Damping
1	+	+		××	
2	+	O	×	×	××
3	+	−	××		
4	O	+		×

7	−	+		×	
8	−	O			
9	−	−	×		

+—Increase
−—Decrease
O—No change
×—Probable cause
××—Most probable cause

Figure 4. Noise spectrum of the transformer with 60-cycle excitation after the elimination of resonance

C. Noise level—64.9 decibels
A. Weighted noise level—53.0 decibels

When the transformer is tanked, most of the vibrations are transmitted from the core and coil assembly through the oil. The magnitude of these vibrations are decreased by the damping forces in the oil. Other vibrations are transmitted directly to the tank wall by the structural members which support the core and coils in the tank with very little damping.

By comparing both the physical noise level and the harmonic index before and after tanking, the extent of resonance can be determined. If the harmonic index has decreased, it indicates that high harmonic resonance may exist, and the change in the physical noise level will show to what extent it exists. Table I has been prepared to show the several different changes that can take place and their most probable cause. Item 8 represents the ideal case in which the physical noise level is decreased, while the harmonic index remains practically constant.

After resonance has been eliminated and the harmonic index remains practically constant before and after tanking, the change in the physical noise level is an indication of the damping merits of the oil and the core and coil assembly supports.

For the example in which the harmonic analysis was used, the physical noise level of the core was 68.9 decibels and the harmonic index was 11.4. For the finished transformer, the physical noise

level was 65.3 decibels and the harmonic index was 9.5 decibels. This particular case falls under item 9, which indicates high harmonic resonance. After changes were made in the mechanical structure, the physical noise level was 64.9 decibels and the harmonic index was 11.9, which then falls under item 8 as a satisfactory point. The relative merit of damping forces (the difference in physical noise before and after tanking) in this particular case is 4.0 decibels, or the vibrational amplitude was decreased to 63.1 per cent of its original value.

Summary

1. The optimum in noise generation is dictated by the magnetostriction characteristic of the steel used, the operating flux density and the physical characteristics of the core structure.

2. The harmonic index and the physical noise level provide a simple method for the practical investigation of resonance in transformers.

3. The elimination of resonance in transformers through the use of these methods will lead to a quieter transformer.

4. This method also provides a means for evaluating the attenuation effect of damping forces applied to transformers.

Discussion

C. S. Murray (Consolidated Edison Company of New York, Inc., New York, N. Y.): The authors have demonstrated how the harmonic index can be used as a tool by the manufacturers for detecting resonance of the transformer structure.

Figure 1. Harmonic index of noise components

There is a possibility that the harmonic index also may be used as a tool by the user for obtaining an idea of the harmonic content of the noise emitted by his transformer.

In order to evaluate any noise, its harmonic content should be obtained, and the harmonic analyzer is considered as the best means for doing this. In many cases, however, a harmonic analyzer is not available and in other cases time does not permit the analysis of the noise at several positions around the transformer.

Most sound level meters are equipped with both the "flat" and the 40-decibel weighting networks wherein the value for either scale may be obtained by the mere operation of a switch. The extra time consumed by obtaining the sound level for the "flat" scale in addition to the value for the 40-decibel scale, when determining the average sound level of the transformer, is small. Furthermore, no additional training of the tester is required.

For convenience, the harmonic index as a function of pure tones is given in curve form in Figure 1 of this discussion. This curve is derived from the response characteristics of the sound level meter. The value of the harmonic index at the different frequencies is the same as used by the authors in their paper.

Figure 2 of the discussion shows the value of the harmonic index at various positions around a 60-megavolt-ampere transformer obtained by taking the difference in the indications of the "flat" and 40-decibel scales. It will be noted that the average value of the harmonic index is 6.5 and by referring to Figure 1 this indicates a transformer noise frequency of 360 cycles. An actual analysis of the transformer noise at various distances from it showed that the outstanding component was 360 cycles. The average value of the index obtained with the cooling fans in operation is practically the same as the case without fans indicating that the transformer noise is still the outstanding noise. An analysis of the noise at various distances from the transformer substantiated this conclusion.

Figure 3 of this discussion shows the value of harmonic index obtained for a 50-megavolt-ampere transformer installation. These results also show the possibilities of using the harmonic index.

It is recognized that sufficient data has not been presented here to determine the limitations or other possible interpretations of the results that may be arrived at by further use. Its possibilities should not be overlooked by those who do not have harmonic analyzers.

The authors make a statement that "the noise level measured by the 40-decibel response is equal to the noise as determined by the ear." We have not reached the stage where a single weighting network of an instrument is capable of following the characteristics of the human ear. The only time that the 40-decibel weighting network does accomplish this is when measuring a pure tone having an equivalent loudness level of 40 phons and with no other sounds present that may mask it. There is a large difference in the harmonic index value obtained if the value determined by the ear were used in place of the 40-decibel response network. For example, the noise spectrum for the transformer core and coil assembly given in Figure 2 of the paper, shows a harmonic index for the 120-cycle component of 16. If we use the published equal loudness contours of the ear,[2] and also realize that this particular component is not masked by the other harmonic tones present, we would arrive at a value of about nine for the harmonic index.

The harmonic index is simply the difference between the values given on two different scales of the sound level meter. Its value has been demonstrated by the authors and it is not felt that any other interpretation of the harmonic index is warranted.

S. Bennon (Westinghouse Electric Corp., Sharon, Pa.): The authors are to be commended for calling attention to the value of the "harmonic index," introduced by Mr. H. Fahnoe in his Institute paper[1] several years ago. In that paper the usefulness of the harmonic index, both as a parameter in the calculation of transformer levels as well as an indicator of resonance was outlined. Those of us who were associated with Mr. Fahnoe at Sharon have been using the

harmonic index in a manner similar to that suggested by the authors. It is gratifying that the significance of this quantity now is attaining more general recognition.

One valuable feature of the harmonic index which is worth stressing, is its ability to detect important resonances and to ignore those which are unimportant. In commercial sound level testing, resonances are of importance when they raise the overall level of the transformer. A resonance which amplifies a relatively weak harmonic, and, therefore, adds very little to the sound energy, would not be of practical importance, as its effect on the ear also will usually be slight. Since the harmonic index is the difference between the sound levels using "flat" and "40" weighting, the resonances must change either one or both of these levels to produce a change in harmonic index. This selective response of the harmonic index, coupled with its ease in measurement using commercially available sound level meters, make it a valuable tool in practical sound level studies. Inasmuch as a complete harmonic analysis is involved and time consuming, the harmonic index provides the necessary criterion by which those units with important resonances can be weeded out for more thorough investigation.

Some mechanical resonances which occur in transformers are susceptible to calculation with engineering accuracy. One of these is the natural frequency of the transformer core as a closed-frame type structure. Although the frequency of a structure of this type is a function of the width of leg divided by the length squared, as stated by the authors, it is well to keep in mind that it is a function of other factors as well. The natural frequency of a rectangular frame with legs of length l_1 and l_2 can be expressed as[3]

$$f=\frac{(K_2)^2}{2\pi l_2^2}\sqrt{\frac{E_2 I_2}{m_2}} \qquad (1)$$

where E_2, I_2, and m_2 are the modulus of elasticity, moment of inertia of the cross-section and mass per unit length, respectively, of the leg of length l_2. For the usual case where the distributed parameters (E, I, and m) of the two legs are equal or bear a constant ratio, K_2 is a function of the ratio of the two leg lengths which we can designate as r. If we assume that the legs are of rectangular section (shell form) or of approximately circular section (core form) equation 1 reduces to

$$f=CF(r)\frac{W_2}{l_2^2}\sqrt{\frac{E_2}{D_2}} \qquad (2)$$

where C is a constant having a different value for core or shell form, $F(r)$ represents a function of the ratio of leg lengths, and W_2 and D_2 are the width and density respectively of leg l_2. Equation 2 indicates that even for a specific type of core and a fixed core material, the natural frequency will still be a function of the ratio of leg lengths as well as the ratio of leg width to the length squared. By choosing the subscript 2 to identify the longer of the two legs, the variation of $F(r)$ with r can be considerably reduced. This may sometimes tend to obscure the dependence of the frequency on the ratio of leg lengths when a limited range of r is considered.

F. Von Voigtlander (Commonwealth Service Inc., Jackson, Mich.): The matter of audible noise from power transformers has been of recurrent interest during the past 20 years. R. H. George's paper given in 1931,[1] outlined many of the factors influencing noise in transformers and methods for noise mitigation in the transformers and in substation installations. A. P. Fugill's paper given in 1934,[2] and E. J. Abbott's paper given in 1935[3] outlined in some detail the successful mitigation of transformer and regulator noises in the equipment itself and in the substation installations.

Much of the work done and reported in

these papers is applicable to the problems of today, though there has been notable improvement in the technique of sound measurements and in the convenience and availability of sound measuring equipment in the meantime. Everyone seriously interested in this problem should review these papers and their references, including the references to the publications of the British Institution of Electrical Engineers, as considerable work in this field was done in England a number of years ago. In a recent paper by C. S. Murray,[4] he reviewed the subject rather well and provided an extensive bibliography of pertinent references.

The accent on the transformer noise problem in the past two years has undoubtedly been stimulated by the increase in flux densities in use in modern transformers in order to take better advantage of the superior properties of modern magnetic materials and construction methods. The great increase in the number and size of transformers being located in residential areas also is a very important factor in the problem.

Various writers have noted that noise level differences as little as 5 decibels have been sufficient to change customer complaint to customer satisfaction. One of the more widely used sound level meters is inherently limited in accuracy and its readings cannot be relied upon for values closer than ±2 decibels. This instrument does not integrate the effects of complex sounds accurately, particularly at the higher levels. There have been a number of references made that the use of the 40-decibel network gives values of noise that are much too low in practice and as a result Mr. Mutschler and Mr. Madden propose the "harmonic index." This approach has interesting possibilities, but it does not surmount the inherent limitations of some sound level meters and it therefore seems of less promise than the authors hoped for.

The writer believes that as a first step a better sound level meter should be used particularly as much better instruments are now available commercially at prices that come within the scope of the usual laboratory budget. Having a better instrument, the use of a flat response network should give consistent and adequate accuracy within the range of frequencies and levels that are of interest in transformer noise measurements. It should then only be necessary to revise the tabulations in the NEMA Standards to reflect more adequately the response characteristics of the human ear, the noise producing characteristics of transformers of various types and sizes, and the measurements made with a better quality flat response instrument.

Relating allowable noise levels to the kilovolt-ampere rating of transformers of a given type and voltage range seems reasonable as size would be proportional to kilovolt-ampere rating, and noise frequency characteristics would have a tangible relationship to size. The larger transformers would be expected to produce a greater proportion of noise in the lower frequency brackets, where the human ear is less sensitive, while the smaller transformers would be expected to produce a greater proportion of noise in the higher frequency brackets where the ear is more sensitive. For this and other reasons the larger and higher voltage transformers should be allowed a higher noise level than the smaller and lower voltage transformers similar to the way the standards now are set up. Considerable field testing would probably be required to properly establish these relationships.

The introduction of new units, new methods of measurement, and types of standards seems to be very much more involved than is necessary. All that is really needed is to use a better instrument and to realign the standard tables of allowable noise limits to reflect the facts of life.

While low level of transformer noise can be very important in those few cases where transformers are located in quiet residential neighborhoods, it would not seem economically justified to increase the cost of standard transformers for the sake of getting them all down to an ideal noise level. The usual compromise of as good a job as we can get without appreciable increase in cost would seem to be in order here just as it has been in so many other engineering matters. Where very low levels of noise are required the extra cost of such provisions would have to be justified by the particular circumstances. Excessive transformer noise just as excessive noise from any other equipment, may properly lead one to question the adequacy of the design or construction, so that reasonable noise levels may well be taken as one of the attributes of product quality.

W. H. Mutschler, Jr. and **T. F. Madden:** Mr. Murray demonstrates that the harmonic index also can be utilized by the user as a tool for the investigation of audio noise. Both Mr. Murray and Mr. Bennon agree that the harmonic index can be obtained in a comparatively short time requiring only a simple operation by the tester, and that it should not be overlooked as a tool when noise investigations are to be made.

It should be noted that the harmonic index versus frequency characteristic depends upon the weighting network of the particular sound level meter used. From the standard tolerances of the *A* and *C* weighting networks, it can be seen that a typical harmonic index versus frequency curve should be used with caution. The harmonic index will indicate the predominant frequency in a noise spectrum providing that the noise levels of all other frequencies are somewhat less than the noise level of the predominant frequency. If there is more than one predominant frequency, the harmonic index cannot correctly be identified with any one of the predominant frequencies, and it will indicate a frequency between the two extreme predominant frequencies. This agrees with the data presented by Mr. Murray in Figures 2 and 3 of his discussion.

The harmonic index as measured by the sound level meter will be equal to the harmonic index as measured by the ear only under certain conditions. However, the important factor is that even though these harmonic indexes are not equal, they will vary in the same manner. That is, the harmonic index in either case will decrease with increasing frequency up to approximately 1,000 cycles and increase with increasing frequencies above this value.

The feature of selectivity as described by Mr. Bennon further emphasizes the value of the harmonic index as a means for quality control in commercial noise testing of transformers since resonant conditions can be located with ease.

Mr. Bennon concurs that the investigation of audio noise is not entirely experimental and can be treated in part analytically and that methods readily usable by the design engineer are available for the determination of the frequencies of resonance of the core.

In the past, various compromises have been suggested for transformer noise measurement. As Mr. Von Voigtlander indicates, the basis for these proposals has been that the *A*-weighting curve does not exemplify the ear response for all intensities. The harmonic index was not proposed as a compromise method of measurement but rather as a means for investigating transformer noise and its elimination. One might conceivably use the harmonic index as a basis for determining a correction factor to be applied to the flat response to determine a sound level which would be nearer to the response of the ear. However, the determination of this correction factor might be rather involved.

Although the use of the flat response has been suggested, it will not overcome all of the inadequacies of the 40-decibel response. For example, consider two transformers; one having a predominant 120-cycle noise and one having a predominant 360-cycle noise, both transformers having a physical noise level of 70 decibels. By studying the equal loudness contours[1] it can be seen that the first transformer will have a loudness level of 60 phons and the second transformer will have a loudness level of 69 phons. Obviously, the second transformer might result in noise complaints when installed in a residential district.

It is to be noted that the method of noise investigation set forth in the paper is based upon using the same sound level meter for all the tests. The inherent inaccuracies of the instrument used will therefore be either completely eliminated or at least their effect will be reduced to a point well within the acceptable limits of engineering accuracy.

Audio Noise in Transformers in Residential and Commercial Areas

C. E. BAUGH
FELLOW AIEE

A DISCUSSION of utility problems, past and present, with transformer noise is given in this paper. In general, its scope is limited to outdoor unit substations of conventional design in sizes ranging from 2,000 to 4,000 kva with primary voltage ratings of 12,000 or 23,000 volts. Sound level data from installations on the Pacific Gas and Electric Company system and corrective measures applied to units having objectionable levels are discussed. Steps which manufacturers might take to minimize users' troubles are suggested.

Transformer Noise and Utility Operations

The Pacific Gas and Electric Company has in operation in the suburban and metropolitan areas adjoining San Francisco Bay about 70 unit substations, 2,000 to 4,000 kva, with primary voltages of 12,000 or 23,000 volts and secondary voltages of 4,160 or 4,330 volts. It operates about ten similar units in smaller communities and in addition has in operation 25 3,000- and 5,000-kva units in rural areas or on the outskirts of smaller cities with a primary voltage of 60,000 volts and secondary voltages of 4,330 or 12,470 volts.

Studies made some years ago indicated the economic desirability of handling load growth in urban and suburban residential or light commercial areas, already served at 4 kv, by installing unit substations to increase the input to the 4-kv system as an alternative to increasing the capacity of existing stations and constructing additional 4-kv feeders. To date this program has met the problems imposed by a tremendous postwar growth in load in such areas with respect to an economic utilization of time, manpower and capital.

The first 2,000-kva 12/4-kv unit substation was placed in operation in 1939 and a few units were installed in the ensuing years prior to the war, but the bulk of the units now in service have been installed since 1945.

If full advantage is to be taken of the various economies of the unit substation type of construction it will be necessary to install many units in areas zoned for residential or commercial occupancy.

In fact, many commercial zones outside of congested downtown areas extend only a half a block either side of a business thoroughfare, the remaining half blocks being zoned for residential use. As a result, transformer sound level is a matter of concern in the majority of the cases where the use of unit substation construction, particularly at primary voltages under 40 kv, is desirable. The alternative to holding sound levels down is to increase the cost of doing business by the amounts necessary to house substation equipment or attenuate sound levels by other means.

Sound Level Data from Pacific Gas and Electric System

The first complaint occasioned by noise from a 2,000-kva unit substation was in 1941. This unit was installed on the rear end of a 30 foot by 73 foot lot between two 2-story apartment buildings, the only complaint registered being from the occupant of a second floor apartment. Sound level measurements made with a General Radio sound level indicator in the manner specified by National Electrical Manufacturers Association rules showed an average sound level of 58.3 decibels, with an average ambient of 42.6 decibels. Figure 1 shows the lot on which the unit was located and shows the adjoining buildings. The original unit has been replaced with the 4,000-kva unit pictured, and no illustrations of the original installation are available. Figure 2 is a plot of the buildings adjacent to the lot and includes sound level measurements with and without the unit energized.

Except for a few other complaints, only one of which was serious enough to require corrective measures, see Figure 3, no particular trouble was experienced until 1948 when we installed the first of a

group of 2,000-kva units built to the same general specifications as previous units but with high permeability cold-rolled steel cores.

Two of these units, installed in commercial zones but with residences on adjoining lots, immediately gave rise to complaints and prompted a general investigation of sound levels of a representative group of similar units. A General Radio sound level indicator was used and all measurements were made in strict accordance with the methods outlined in National Electrical Manufacturers Association Standards for Transformers.[1] No readings in locations where the ambient sound level was less than 7 decibels below the level of the ambient plus transformers have been included in the following data and very few of the readings have been adjusted for ambients between 7 and 10 decibels lower.

All measurements were made without fans or tap-changing equipment in operation.

The results of these investigations are plotted in Figure 4 and summarized in Table I.

All of these units have met the manufacturer's guaranteed values of 64 decibels for delta-Y connected transformers and 65 decibels for delta-zigzag connected transformers, but the only units known to have high permeability cold-rolled steel cores (those built by manufacturer *A* in 1948) show considerably higher sound levels than earlier units from the same manufacturer.

Measurements on one 4,000-kva 12/4-kv unit substation built by manufacturer *A* in 1948 to the same general specification as the four 2,000-kv units built in 1948 show a sound level of 49 decibels at an ambient of 34 decibels. Sound levels 19 feet from this unit with no shielding average 37 decibels. We are informed that the core in this unit is of ordinary silicon steel.

The data in Figure 4 and the summary, Table I, indicate a significant increase in noise level in units which have cores operating at flux densities higher than the earlier silicon steel cores. In this connection it is of interest to note the following statement from what appears to be a final report to the members of the Electric Equipment Committee of the Edison Electric Institute in March 1938. The statement reads in part:

"Apparatus noise levels will be dropped from our program as an active subject. The following observations indicate the reasons for this action: "..... We are therefore primarily concerned with the noise emanating from transformers located in network vaults and indoor and outdoor substations, the latter especially in residential areas.

"As previously stated, the noise produced by such installations is generally tolerable with transformers of the more modern (quiet) design....."

Undoubtedly this was a correct conclusion in 1938, but the development of new core steels which have permitted the use of higher flux densities without a corresponding increase in losses points toward the necessity for reopening the subject.

The sound level of one of the 1948 units occasioning a complaint is 61 decibels, and of the other 57 decibels. Other units that have been the cause of complaints show levels of 58.3, 55.5 and 54 decibels. No complaints have been oc-

Complaint from occupant of building at left. Sound level, 61 decibels

casioned by units having sound levels below 54 decibels although many of them are as close to residences as ones that have caused complaints. Other units are situated in areas not yet built up and it is possible that we will receive additional complaints when adjoining lots have been occupied.

Tentatively the conclusion has been reached that units with sound levels of 52 decibels or lower should be satisfactory for installation in residential areas unless reflection from adjoining buildings or walls serves to increase the intensity in a given direction to an undesirable value. Another tentative conclusion has been reached to the effect that complaints will not be serious if the operation of transformers in residential areas does not increase the sound level at points adjacent to adjoining buildings to values in excess of about 36 decibels.

As a matter of fact the sound levels specified in National Electrical Manufacturers Association standards are not realistic for unit substations of ratings suitable for outdoor installation in residential areas. These levels are so high that trouble can be expected from any unit whose level approaches the permissible value.

At this point it is not out of order to reiterate certain comments on the matter of taking sound level measurements. Considerable trouble has been experienced in collecting data and care is necessary if they are to be reasonably accurate. To avoid ambient sound levels that are higher than those prescribed in National Electrical Manufacturers Association rules, measurements frequently must be made at night, and reliable readings cannot be taken, even then, during periods when there is traffic on the street in front of a station. Children at play, dogs, birds, and traffic interfere with daytime measurements; crickets, other night life and traffic interfere with night measurements. Reliable data cannot be secured in a high wind or when it is raining. Instruction and some experimentation is required before the average observer can produce dependable and reasonably consistent readings.

Corrective Measures

Barriers and Housings

It has been necessary to apply corrective measures to three installations on the Pacific Gas and Electric system and studies are still under way to determine the best and most economical method of affording relief in other cases where conditions are severe enough to warrant correction.

As an emergency measure the 2,000-kva unit originally installed in the location shown in Figure 1 was enclosed by a structure about 12 feet high with adobe walls but no roof. This reduced the sound level to an acceptable value although the complainant, apparently very sensitive to noise, was not entirely satisfied. Subsequently she moved away and no complaints have been received from the new occupant of her apartment or from any other resident in either of the adjoining buildings. The 2,000-kva unit recently has been replaced with the 4,000-kva unit shown in Figure 1 with a sound level of about 49 decibels; no complaints have been received since the change.

Figure 3 shows two 2,000-kva unit substations in an enclosure consisting of walls about 12 feet high of hollow concrete blocks filled with sand and a concrete slab roof with an 8-foot square opening over each transformer. This housing eliminated all complaints from occupants of the two adjoining apartment houses. No records of sound level measurements at this location are available.

Figure 5 shows a unit substation manufactured in 1948 with a sound level of 61 decibels, installed on a narrow lot in a commercial zone, the other half of the block being zoned for residential occupancy. Complaints of undue noise were made by the occupant of sleeping quarters in the rear of the small store on the left. Occupants of single family dwellings on lots facing the next street did not find the noise objectionable.

Due to difficulties encountered in ventilating units completely surrounded by walls, experiments with a movable barrier were conducted to determine the effectiveness of partial barriers and the location of such barriers with respect to a unit for optimum results. Use of a sound-absorbing material for the barrier was considered but, to date, no material suitable for outdoor installation has been found. The objections to a hard-surfaced barrier are: the build-up of sound level on the transformer side of the wall which results in a less efficient attenuation; and the increase in intensity on the side of the unit opposite the barrier.

A portable barrier of plywood was located at distances of 30, 42, 53, and 63 inches from the side of the unit which is not equipped with radiators and Figure 6 shows the results of sound measurements made with this barrier in place. Levels adjacent to the barrier were naturally higher than measurements at the same point without the barrier. A distance of 45 inches from the sides of unit, on which no radiators are mounted, proved to be the best location for this particular unit, although this dimension is not critical. Other measurements were made on the radiator side of the unit but the sound pattern is so distorted by the radiators that it is impossible to secure results as definite as on the other side. In this particular case, distances of 6 feet–4 inches and 9 feet–3 inches gave equally good results, but more experiments with other units are necessary before positive conclusions can be drawn.

Figure 6 shows the permanent 2-sided

Figure 6 (left). Sound levels with barriers in place—2,000-kva unit

Sound level, 57 decibels

barrier which consists of a wood frame faced with flat transite sheets and filled with rock wool. Figure 6 shows sound patterns between the unit and the permanent barrier. This construction was effective in reducing the sound level in the vicinity of the complainant's quarters to an unobjectionable value, and build-up in the opposite direction due to reflection was not noticeable except close to the unit. The cost of such a barrier 12 feet high will be on the order of $18.00 per lineal foot. It is estimated that a 4-walled, roofless cubicle of hollow building blocks can be built for about the same total cost if the length of the partial barrier is much in excess of 30 feet. Ventilation problems make a 4-walled cubicle undesirable and increase costs unduly. If ventilation is not provided, transformer loading must be held down; if ventilation is provided other noise problems arise.

Resilient Foundation Pads

Tests were conducted on a similar unit to determine the attenuating effect of a resilient pad between the unit and concrete foundation. Redwood planking was used on one unit, a $^3/_8$-inch thick sheet of a patented synthetic resilient material on another. Measurement of attenuation from the I-beam base of the units to the concrete foundations showed no significant improvement, as values were of the same order of magnitude as similar measurements on a unit installed on an identical foundation without pads. Sound level measurements made at property lines indicated a possible maximum decrease of about 3 decibels in the sound level of the unit installed on a synthetic resilient pad, although there was no perceptible reduction in audible noise. Apparently other utilities have had better success with resilient pads and further experiments are proposed.

Interior Linings

The inside surfaces of the walls of cable terminal compartments, circuit breaker compartment, and tap changer control compartment of one unit were lined with "acoustic" sheets chosen for fire-resistant qualities and mechanical suitability for this application. Sound level measurements indicated a reduction in sound level of about 3 decibels on the *A* scale and 1 decibel on the *B* scale in front of the treated surfaces. From the standpoint of auditory sensation the improvement was more noticeable than when resilient pads under units were used.

Equipment Construction

Radiators, doors, thin side panels on compartments and other mechanical details tend to contribute to over-all sound output. The sound level of several units has been reduced materially by tightening loose parts, improving the fit of doors, rebracing radiators, and so forth, but it should not be necessary for the user to apply remedies of this character.

Manufacturing Problems

Measures to reduce sound level available to the user are relatively few in number and are of the nature of "locking the barn door after the horse is stolen". The most effective measures applicable to unit substations are expensive, tend to be unsightly unless excessive expenditures are made, are liable to interfere with the use of equipment at its maximum output on a temperature-rise basis and complicate the performance of major maintenance and repair operations. There is much to be said for the unit substation as an answer to many distribution problems, but sound level will become an increasingly important factor if utilities are to take full advantage of the good qualities of this form of construction.

Evidence so far indicates that transformers with cores operating at high flux densities will be significantly noisier than earlier units. The efforts of manufacturers to reduce costs by this attack are appreciated but associated noise problems will require the attention of our most capable transformer designers and continued co-operation by the manufacturers and users if the maximum benefit from these cost reductions is to be obtained.

The fundamental cause or causes of transformer core noise need further study. While magnetostriction has been accepted generally as responsible, it is understood that recent experiments indicate that this quality is not the sole source of core noise. The development of quieter cores must depend on a more complete knowledge of the mechanics of noise generation in transformer steels.

Many publications, particularly some of European origin, point to the possibility of introducing features such as internal baffles, sound absorbent internal

tank linings and resilient mountings for core and coil assemblies to reduce sound transmission from core to tank walls. Vibration dampers have been suggested as a possible method of attack on core noise at its source. Tank designs should be watched to be sure that walls will not resonate at the frequency generated by the core. Radiators, doors, and other accessory parts, compartment walls, and so forth, should be so designed and assembled that they will not increase noise output. Attention to these details should not increase costs materially. Careful control of assembly methods and some attention to core and coil design should eliminate clamping structures as an incidental source of noise without causing an appreciable increase in costs. As an indication that sound level can be reduced by attention to detail, we have observed a variation of sound level in units furnished by the same manufacturer to the same specification and in the same year of as much as 12.5 decibels.

A joint study of presently specified standard sound levels, especially as applied to unit substations of ratings suitable for installation in residential and commercial areas should be undertaken. A maximum level on the order of 65 decibels is not realistic under these circumstances. Of all the 2,000-kva units we have purchased, one unit measured 61 decibels, the remainder under 60 decibels. A 60-decibel guarantee would have increased the cost of the transformer part of these substations by 10 per cent, a 55-decibel guarantee by 25 per cent. At the moment we see no advantage commensurate with the increased costs in specifying a lower sound level than standard, but this does not mean that we are complacent with respect to the increase in measured levels of recent units.

Attempts have been made to check some of our field measurements by comparison with factory test results. One manufacturer had not made a factory measurement of sound level on any units furnished us since 1945, and a second manufacturer had made such measurements on one unit only. As levels approach the guaranteed maximum and in view of the variation in level of units of the same design, it appears that more routine factory checks of sound level will be necessary.

Presently available sound level indicators are not entirely satisfactory as indicators of the noise level of transformers insofar as the effect on the average human ear is concerned. Standard sound level indicators are provided with three weighting networks, a "40" network, *A* scale, for sounds up to 60 decibels, a "70" network, *B* scale, for sounds from 50 to 90 decibels and a flat network, *C* scale, for sounds from 80 decibels up. A choice of networks is made on the basis of the level expected at the ear of the nearest observer and on this basis the "40" network is specified by National Electrical Manufacturers Association rules for use in measuring transformer sound levels. However, the same rules specify that measurements are to be made 12 inches from the surfaces of sound-producing equipment, and the "40" network cannot be expected to represent the effect on the ear of an observer some distance away of sounds which can reach the 83-decibel level at 12 inches in large high-voltage transformers. Measurements of the same sound will, in general, be higher using the "70" and flat networks than when the "40" network is used.

So many frequencies are present in transformer sound that observations of various units made by ear do not always check with measurements. One unit substation on our system that was rated as quiet by a group of observers had a higher measured sound level than another unit rated as noisy by the same observers.

Further consideration of the prescribed sound levels of transformers and methods of measurement to be certain that they represent the best possible correlation between measured quantities and the effect on the average human ear might result in considerable improvement insofar as consistency of end results is concerned. The development of a sound level meter that will permit a more realistic approach to the problem of transformer noise might be impractical, but certainly merits some thought on the part of acoustic engineers.

Conclusions

Widespread use of unit substations in or adjoining residential areas has focused attention on the noise generated by the transformer portion of these units. The problem, apparently, has been aggravated by the use of higher flux densities made possible by the development of new core steels. Smaller core and coil structures tend to reduce the cost of transformers, but part of this saving will be lost if higher sound levels in unit substations interfere with their use in residential areas.

Following complaints of objectionable noise, an investigation of sound levels of unit substations on the Pacific Gas and Electric Company system resulted in the following tentative determinations:

1. Units of the same design show a wide variation, as high as 12.5 decibels, in sound level.

2. Units with cold-rolled steel cores have an average sound level about 7.5 decibels higher than that of earlier units built to the same specifications.

3. If unit substations have an average sound level of 52 decibels or lower or if their operation does not result in a sound level higher than 36 decibels at points adjacent to nearby residences, the noise should not be objectionable.

The most effective corrective measures are 4-walled enclosures with or without complete or partial roofs. Sound bar-

Figure 9. 4,000-kva unit substation—no complaints
Sound level, 49 decibels

riers are effective if complaints are from one or two directions only. Enclosures interfere with air circulation and are unsightly unless unreasonable expenditures to improve appearance are made. The housing of unit substations is contrary to the philosophy under which this type of apparatus was developed.

Unreasonably wide variations in the sound levels of unit substations built to the same specifications in the same year by the same manufacturer suggest that more attention to design details and assembly methods is necessary, particularly if higher flux densities are used. Continued investigation of the fundamental nature of transformer noise is suggested, also the investigation of methods of reducing external sound levels by the use of internal baffles, tank linings, resilient core and coil mountings, vibration dampers, and so forth.

A review of prescribed standard sound levels of unit substations having ratings suitable for installation in residential areas and of the prescribed methods of determining sound levels might be in order.

Discussion

T. D. Gordy (General Electric Company, Pittsfield, Mass.): The data presented by Mr. Baugh show the importance of low noise level of transformers located in residential and commercial areas. The introduction of cold-rolled steel as a cost reduction measure has increased transformer noise levels. As Mr. Baugh points out, the manufacturer is being challenged with continuing the use of cold-rolled steel and reducing noise levels simultaneously without seriously decreasing cost reductions obtained. Manufacturers must accept this challenge even though modifications necessary to reduce noise are reflected throughout most of the transformer design. This is a serious problem facing the manufacturer.

Mr. Baugh has arrived at an average sound level of 52 decibels or lower for substations not causing noise complaints. Due to construction arrangement of component parts, in some installations transformer noise level and substation noise level may be the same figure; for other installations, transformer noise levels would be different from substation noise levels. It would be worthwhile to know if the 52-decibel level applies to the substation as a whole or specifically to the transformer as measured under present NEMA specifications.

In the paper, installations are described to which noise barrier walls were added. Measurements taken between the transformer and the wall are given. If data are available, it would be interesting to know if noise reduction at the complaint has been correlated with the dimensions of the wall and the spacing of the wall relative to the transformer installation.

Noise requirements of the operator and utilization of improved materials of transformer construction appear to conflict. An economical solution satisfactory to both operator and manufacturer will have to be reached. A logical method of obtaining this solution is by close co-operation of manufacturers, operators, and national working committees. Presentation of data such as Mr. Baugh has presented is necessary for the successful operation of such committees.

E. G. Fischer (Westinghouse Research Laboratories, East Pittsburgh, Pa.): The paper by Mr. Baugh is important because it mentions something about all of the important factors in the transformer noise problem. It is gratifying to note that while the author is presenting the problems of the user, he also acknowledges the achievements of the manufacturers in keeping down unit costs and in supplying him with many units substantially below NEMA levels. The author's contributions made in the form of sound level data on practical noise-corrective transformer enclosures are of general value and much appreciated.

The author properly suggests "steps which the manufacturers might take to minimize users' troubles."

The writer is encouraged by Mr. Baugh's fair-minded criticisms; his acknowledgment of the possible savings to him introduced by the use of cold-rolled steel cores is a reasonable approach. The point is that manufacturers have developed new and better magnetic materials, but the users should decide what part of the resulting cost saving should be turned back to reduce noise level, and what part should be reflected as reduced cost to the user.

The author reports an upward noise level trend over the past few years from 51 to 59 decibels, which he feels requires housing of unit substations in residential areas, and yet all of the transformers under discussion have met the NEMA level of 64 to 66 decibels. Unless otherwise specified, the manufacturer designs all recently constructed units to meet the NEMA sound levels which are very realistic to him since he must meet them on highly competitive equipment. To establish industry noise levels such that all transformers are suitable for installations in quiet residential areas would mean increased cost for users, including many to whom the higher cost will be much more objectionable than the higher sound level. It is certainly fair to suggest that the increase in noise level reported may not be the fault of cold-rolled steel, rather it may well be a matter of economics; that is, with the ever-increasing cost of labor and materials and with the desire to keep down the sales price, the manufacturer may have been impelled to permit the noise level to approach NEMA levels. It is interesting to note that Mr. Baugh questions if a 3-decibel reduction is worth a 10 per cent increase in cost, or if a decrease from 64 to 55 decibels is worth a 25 per cent increase in cost. It is my understanding that these cost increases are much too low in many instances. This of course supposes the reduction to be achieved by reducing induction, after such factors as loose rattling parts or resonances have been eliminated. Since the cost of noise reduction is becoming more of a general problem, then as Mr. Baugh has suggested, close co-operation between manufacturer and user would be helpful in order to get a realistic solution to this problem. Such a solution could relate permissible levels to various applications and would of necessity consider transformer cost versus sound barrier cost.

In a general sense, noise problems are not new to the manufacturers of competitive electric equipment. It is a common research experience that noise problems are never solved completely where an industry is striving so hard, as the transformer industry, to keep down the cost of its product. With more knowledge about how to reduce noise, the manufacturer has the problem as to whether he will keep down the costs with the same noise level and satisfy one part of the industry or reduce noise level to satisfy another part. It is obvious no single solution will please everyone. The situation with regard to transformers is particularly difficult because the designs have been worked over by experts for a long time. The writer was once so rash as to suggest using a more viscous transformer oil to attenuate the noise transmission from core to tank. As most of you know, there are probably a dozen reasons, all of them good ones, why you cannot change the oil. Similar restrictions apply to all the other important features of transformer designs. In spite of the great amount of effort expended on the problem, at present there does not appear to be a radical solution to transformer noise in sight.

I would like to assure Mr. Baugh that all of his constructive suggestions to the manufacturers will receive careful consideration. The writer personally feels that further investigations of the use of external enclosures is desirable. This is a new field where the designer has lots of freedom, and its potentialities should certainly be examined in the light of the cost reductions possible by the full utilization of better magnetic materials. We believe Mr. Baugh infers a joint supplier-customer responsibility when he suggests a co-operative approach to the problem between manufacturers and users. Such a proposal will be helpful to the industry as a whole, for there is much in the noise problem that requires mutual consideration and evaluation.

E. A. Blomqvist (Consolidated Edison Company of New York Inc., New York, N. Y.): Mr. Baugh indicates that a transformer that produces a sound level of 36 decibels at a residence should not be objectionable. Our

TRANSFORMER
5000 KVA 26400/4560 VOLT
OIL FILLED, SELF COOLED
NEMA SPECIFIED SOUND LEVEL-67 DB
NEMA MEASURED SOUND LEVEL-65 DB

experience indicates that even lower values are necessary to insure freedom from complaints.

It has been our experience that it is the pitched note emitted by a transformer that causes complaints, even though the level of this note is far below the ambient sound level. For this reason, we have found it necessary to use an analyzer in our sound level measurements, since the pitched note does not add measurably to the ambient level.

A few examples of transformer noise that have caused complaints are listed in Table I of the discussion.

These may be considered borderline cases, but each one of them resulted in a vigorous complaint. It will be noted that all these locations are relatively quiet, and any appreciable increase in the ambient level would have masked out the objectionable pitched note. We have found that a pitched sound that is 20 to 25 decibels below the ambient level can be distinguished by the ear.

From these data, it appears that, to insure complete freedom of complaints, the pitched sound must be kept 20 to 25 decibels below the ambient level, except in quiet locations, where it should be kept below the threshold of hearing, or an absolute level of about 20 decibels. These values are in terms of the 40-decibel network.

Figure 1 of the discussion shows measured sound levels in the vicinity of a unit substation with a 5,000 kva 26,400/4,560-volt oil-filled self-cooled transformer. This transformer has an NEMA specified level of 67 decibels and a measured value of 65 decibels. The sound levels of the various frequency components, as well as the total noise, have been plotted as a function of distance from the transformer. The sum of the various components was calculated and also is plotted.

Table I. Sound Levels Measured in Connection with Complaints of Transformer Noise

Type of Location	Sound Level-Db (40-Db Network) Ambient	Pitched Noise	Frequency of Pitched Noise	Aural Observation
Sound studio	38	24	120	Faint
Bedroom of a residence	36	30	120	Faint
Bedroom of a residence	33	26	120	Clearly audible
Bedroom of a residence	33	20	360	Faint
Quiet office	43	34	120	Pronounced

It will be seen that, at a distance of 96 feet, the transformer noise is 32 decibels, which is only 10 decibels below the ambient level, and consequently can be heard.

These tests show that transformers of this type, having NEMA specified sound levels, must be located on a plot of considerable size so that 150- to 200-foot clearance is provided to the nearest residence, or else a costly barrier or housing must be provided.

C. E. Baugh: The apparent revival of interest in the subject of transformer sound levels, as evidenced by papers and discussions on this subject, is very gratifying, and continued co-operation and exchange of information between manufacturers and users should produce results beneficial to the entire industry.

The sound level data and conclusions presented in the paper deal primarily with unit substations of single-feeder construction in which the transformer, tap changer, and switchgear comprise a unit with a projected floor area, including radiators, which approximates a square. Sound level measure-

ments are the average value of a series of readings taken at intervals around the entire unit. There are, of course, significant variations between readings adjacent to different parts of a unit. Tap changers were inoperative when measurements were made. In cases where barriers have been installed subsequent measurements have indicated that sound levels at points where complaints originated have been reduced to the average ambient levels with transformers de-energized and complaints have ceased. Further experimental work with barriers is planned, but no additional information is available at present.

I agree with Mr. Fischer that, to date, units have not exceeded NEMA levels. The point made with respect to these levels is that they are entirely too high for equipment, such as unit substations, designed for installation outdoors in commercial and residential areas. The logical conclusion to be drawn is that a revision of present values for such apparatus by a joint committee is in order.

It is hard to understand why a guaranteed 5-decibel reduction in NEMA levels is worth 10 per cent extra and a 10-decibel reduction 25 per cent extra, when units built in the same year to the same specifications and design and presumably with cores operating at the same flux densities show a 12.5-decibel variation in sound level. The thought suggests itself that some considerable reduction in levels can be attained by means other than the obvious expedient of reducing flux density.

Mr. Blomqvist's data relating to the effect of pitch on the audibility of transformer noise are decidedly pertinent. In this connection, Mr. Gordy's paper entitled Audible Noise of Power Transformers[1] adds considerably to information along this line. It is interesting to note that measurements of nine transformers tabulated in this paper show dominant sound levels at 120 cycles on 3 units, at 240 cycles on 4 units, at 360 cycles on 1 unit, and at 1,200 cycles on 1 unit. Such data indicate the potential value of a sound level indicator which will measure the audible effects of transformer noise more accurately than present indicators and suggest further investigation of the fundamental causes of transformer noise.

The conclusion that units having a level of 52 decibels or lower should not occasion complaints is stated in my paper as a tentative conclusion. A unit with a sound level of 46 decibels was installed in 1946 on a small lot in a very quiet residential neighborhood in close proximity to the bedroom windows of three 1-story houses. The only shielding was a planting of low shrubbery around the property lines. This installation has not given rise to any complaints.

Complaints that have arisen have been due to units with sound levels higher than 52 decibels installed in commercial zones or in apartment house areas on the fringes of commercial zones where the ambient level is higher than the level to be expected in a quiet residential area. A number of units with relatively high sound levels have been installed on lots in residential areas at some distance from presently constructed residences and additional complaints are expected when adjacent lots are occupied. It is almost certain that the installation near residences of units having sound levels that approach standard guaranteed values will occasion complaints in at least nine out of ten cases. We feel that further experience might indicate that levels considerably lower than 52 decibels are desirable in some cases, but that a level on that order will satisfy requirements in many locations.

The author wishes to take this opportunity to thank Messrs. Gordy, Fischer, and Blomqvist for their constructive comments and suggestions, particularly with respect to the necessity for a co-operative approach to the problem.

Generator Rating of Induction Motors

OTTO J. M. SMITH
MEMBER AIEE

ENGINE-driven induction generators were ideal power sources for those industries and farmers required to curtail their demands during the power shortage in northern California in the spring of 1948. The advantages of the induction generator were: simplicity of control apparatus, freedom from hunting, no exciter required, no synchronizing required, low fault currents, low cost, and subsequent general usefulness in later motor applications.

The nameplate data on most induction machines would be motor ratings, and it is desirable to consider what changes must be made, if any, in order that the machine operate satisfactorily as a generator. If the speed is driven above synchronism by the same revolutions per minute that the machine normally operates below synchronism, the generator will deliver approximately rated current at rated voltage and rated efficiency. The electric power out will be approximately equal to the rated shaft motor power. The generator power factor will be much worse, being approximately equal to the motor power factor times the motor efficiency.

Typical Generator Rating

The approximate gross changes when using a 1,000-horsepower class A induction motor as a generator can be followed with the aid of the equivalent circuit shown in Figure 1, and the approximate vector diagram in Figure 2. The primed symbols refer to full load motor operation, and the double-primed symbols to full load generator operation. The terminal voltages, V_t' and V_t'', are equal in magnitude, but are shifted in phase with reference to the internal generated voltage. Figure 2 is drawn for equal rotor currents, so that I_2' and I_2'' are equal in magnitude, and θ_2'' is equal to θ_2'.

It can be seen that the motor generated voltage is less than the terminal voltage, whereas the generator internal voltage is greater than the terminal voltage by the voltage drop in the primary impedance. Therefore, in changing from motor to generator action, the internal flux will increase, because the generated voltage has increased in magnitude by twice the in-phase component of the primary voltage drop in the resistance. This is shown in Figure 2. The change is about 3.5 per cent for a 1,000-horsepower motor (5.6 per cent for 10 horsepower).

The no-load current does not change. The main flux component of the full-load current is proportional to the generated voltage and therefore increases by about 4 per cent of I_m, or about 1 per cent of the rated terminal current. Since for the same rotor current the generator flux is greater than the motor flux, slightly less slip is required.

The primary component of the load current is unchanged in magnitude, but its in-phase component is reversed in direction when the machine is operated as a generator. The load component of current is added to the magnetizing current to give the total primary current. This is shown in Figure 2 for both motor and generator action. The magnetizing component is increased because of the increased flux, but this does not change the total magnitude appreciably. The generator primary current is slightly less than for motor action because it is reduced vectorially by two times the stator core loss current, or is reduced in magnitude by about two times the no-load stator core loss expressed as a per cent of the motor full load input power. Because of small voltage angle shifts not considered in this approximate analysis, the actual current change is one-half of the approximate value. This is less than 1 per cent for a 1,000-horsepower motor (3 per cent for 10 horsepower). A word of caution is in order concerning the stator core loss. This is the core loss which would be measured at exactly synchronous speed. Under full load conditions the total core and stray load loss may be more than twice as much because of the additional tooth frequency losses which are usually large.[1] These losses appear as a magnetic drag and therefore there must be a component of torque proportional to them and a rotor current component to give this torque. In the equivalent circuit of the induction motor, Figure 1, the resistance R_s representing these stray core losses is placed across the load so that it is supplied by current flowing through the rotor reactance and resistance. It is important in considering the change in primary current from motor to generator action, to realize that the core loss component which causes the primary current to vary, is only the stator core loss.

The phase angle of the terminal voltage with respect to the current is altered appreciably by the out-of-phase component of the primary reactance drop. The power factor therefore is considerably less and the reactive kilovolt-amperes are materially increased.

The stator core loss and the stray load losses are increased by 7 per cent and 14 per cent respectively for a 1,000-horsepower motor (11 per cent and 23 per cent for 10 horsepower), due to the increased flux. The rotor copper loss is unchanged. The stator copper loss is decreased by about 2 per cent for 1,000 horsepower (7 per cent for 10 horsepower). The friction loss is proportional to the 3/2 power of the speed, and therefore increases about 5 per cent for 1,000 horsepower (10 per cent for 10 horsepower). The windage loss is proportional to the square of the speed

Paper 50-20, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted May 28, 1948; made available for printing November 29, 1949.

Otto J. M. Smith is an Associate Professor in Electrical Engineering at the University of California, Berkeley, Calif.

The author wishes to express his sincere appreciation to Professor T. G. Tarboux, author of Alternating Current Machinery,[2] for permission to quote the test figures given in Table I.

Figure 1. Exact equivalent circuit of induction machine

G_c is stator core loss conductance only
R_1 is rotor resistance at slip frequency referred to stator
$R_1 = R_{dc}(0.878 + 0.122e^{0.95f})$
$R_2 = R_{dc}(1 + |s|/9)$ at low slip
G_s is stray load loss conductance
$G_s = G_s s^2 + G_s$ at low slip
$G_s = kG_c/(s')^2$, approximately
$G_s = G_s Y_c^2 R_1^2$
k is 0.9 to 1.3
s' is slip at full load motor operation

Figure 2. Approximate vector diagram for induction machine

Small detail is greatly exaggerated. Primed letters refer to full-load motor action. Double-primed letters refer to full-load generator action. The rotor current is the same in each case

but since it is usually smaller than the friction loss, it can be lumped with it and the 3/2-power variation applied to both without serious error.

The effect of all these changes is to give a net increase in the magnitude of the losses when shifting from motor to generator action of only 2 per cent of the losses for 1,000 horsepower (5 per cent of the losses for 10 horsepower). The cooling, however, due to the increased speed, is approximately 3 per cent greater (6 per cent for 10 horsepower), and therefore the temperature rise is essentially the same or slightly less.

The shaft torque is proportional to the square of the rotor current, and inversely proportional to the slip. If the generator is operated at the same rotor current as rated full-load motor conditions, the 1,000-horsepower machine, whose slip is reduced about 2 per cent, will have about 2 per cent more shaft torque (4 per cent for 10 horsepower). The speed increase due to the change in action is twice the slip or 3 per cent for 1,000 horsepower (8 per cent for 10 horsepower). The generator power input is the product of the shaft speed and torque and is therefore about 5 per cent greater than the 1,000-horsepower motor shaft output (12 per cent for 10 horsepower).

For these examples the total motor loss exclusive of friction as a percentage of shaft power output was 5 per cent for the 1,000-horsepower and 10 per cent for the 10-horsepower motor, the latter being more efficient than usual designs. Therefore the electrical output of the generator is essentially the same as the shaft output as a motor. Using this approximation

$$V'' I'' \cos\theta'' = V' I' \cos\theta' \text{ (eff)}' \quad (1)$$

$$\cos\theta'' = \cos\theta' \text{ (eff)}' \quad (2)$$

Primed symbols refer to rated motor conditions. Double-primed symbols refer to generator operation at the same rotor current.

If operated at nameplate terminal current, the generator rotor current would increase by 1 per cent (3 per cent for 10 horsepower), the total losses would increase by 2 per cent (6 per cent for 10 horsepower), but the cooling would only increase by 0.02 per cent (0.1 per cent for 10 horsepower). The temperature rise would go up quickly so it is important to know the correct operating current.

The previous discussion of approximate relationships is applicable only to class *A* motors. It has been shown that a squirrel-cage-rotor, low-slip induction motor designed for reduced-voltage starting can be operated as an induction generator at approximately rated terminal current. This may not be true for high-slip motors, or ones of unconventional construction. For motors over 1,000 horsepower, the exact conditions should be computed. The common types of motors are:

Class *A*—Normal torque, normal starting current.

Class *B*—Normal torque, low starting current (5 × full load *I*).

Class *C*—High torque, low starting current (loaded reciprocating compressors.)

Class *D*—High slip motors (used with flywheels).

Re-rating Equations

Generator characteristics computed on the basis of an equivalent circuit in which the stray load loss was lumped with the core loss, or was neglected, were considerably in error. It was necessary, therefore, to develop the equivalent circuit shown in Figure 1, in which the stray load branch is correctly represented for slips less than one-fifth the synchronous speed.

The important generator computations are current, slip, and temperature rise. Computations have shown that if the generator is operated at the same value of rotor current for which it was designed as a motor, the temperature rise is very near the rated value. Consequently, all subsequent formulas in this paper will be given for rated rotor current, and if their solution indicates that it is necessary to make a slight change in the operating condition, the new values can be computed by incremental methods.

The ratio of the generator to motor terminal current, for $I_2'' = I_2'$, is

$$I_1''/I_1' = 1 - 2(P_c \cos\theta_1'' - I_{oa}^2 R_1)/(VA) \quad (3)$$

where

P_c = no-load primary core loss per phase
I_{oa} = no-load current
R_1 = 60-cycle resistance of the primary
$\cos\theta_1'$ = full-load motor power factor
VA = volt-ampere rating per phase

The motor power factor is the only quantity above which requires a load for its measurement. Fortunately, it is not necessary that any of these quantities be known accurately. If each is within 5 per cent of its correct value, the current-ratio expression will be accurate to 1 per cent. It is necessary, however, to know the exact rated current. This can be obtained from the nameplate, which also will probably state the rated voltage, horsepower, and full-load speed. The total motor losses are

$$\text{Losses} = P_h' = 100\left[1 + \left(\frac{252}{\text{rpm}}\right)^2\right] \times \left[0.045 + 0.01\sqrt{\frac{1{,}000}{\text{hp}}}\right] \text{ per cent} \quad (4)$$

$$(\text{eff})' = 1 - \left[1 + \left(\frac{252}{\text{rpm}}\right)^3\right] \times \left[0.045 + 0.01\sqrt{\frac{1{,}000}{\text{hp}}}\right] \text{ per unit} \quad (5)$$

This empirical efficiency equation is within 2 per cent for the usual class A and B motors from 10 to 1,000 horsepower. This was derived to fit the typical efficiency curves given in reference 6. Wound-rotor and class C motors have efficiencies a few per cent lower, and high-slip class D motors about 5 per cent lower.[6] The motor power factor can be computed from the rated terminal current and the approximate efficiency.

$$\cos\theta_1' = P'/(\sqrt{3}\ V'\ I'\ \text{eff}') \quad (6)$$

Rerating the slip and temperature rise requires a separation of the losses. Typical values of primary core loss are 1 to 3 per cent; of primary resistance, 2 to 4 per cent; and of no-load current, 25 to 40 per cent.

The ratio of the generator to motor slip is

$$-s''/s' = 1 - s'(2 + 9P_s'/P_L' - 6s') \quad (7)$$

P_s'/P_L' is the per-unit stray load loss, and at full load it is approximately equal to the no-load core loss. In high-slip machines, it may be a larger percentage of the total losses. s' is the full-load motor slip. It is the most important constant in rerating a machine, and should be measured carefully if possible. Typical values are 1 per cent for 1,000-horsepower high speed, 2.3 per cent for 400-horsepower medium speed, 3.5 per cent for 15 horsepower, 1,800 rpm; 5 per cent for 5 horsepower, 900 rpm; and 9 per cent for class D, high slip motors.

The ratio of the temperature rises is

$$T''/T' = (1 - 2s')P_h''/P_h' \quad (8)$$

$$P_h' = P_f' + P_s' + P_c' + P_2' + P_1'$$

$$P_h'' = (1 + 3s')P_f' + (1 + 4s')P_s' + P_c' + p_2' + (1 + 80s'^2)P_1' \quad (9)$$

P_h' is the sum of the motor losses contributing to heating. The components, listed in order are: friction and windage, stray load, primary core loss, rotor copper loss, and stator copper loss. The reason the core loss does not appear to vary between P_h' and P_h'' is because the terms accounting for its increase cancelled some equal negative values in the other losses. The copper loss change is an approximation.

The correct expression is given in a tabulation at the end of this paper, called equation 58.

The air-gap torque in synchronous-watts is

$$-T_L''/T_L' = 1 + 2s' + 4P_s'/P_L' \quad (10)$$

The shaft torque differs from the air-gap torque above by the friction loss.

$$T_{\text{out}}' = T_L' - T_f'$$

$$T_{\text{in}}'' = T_L'' + T_f'$$

$$P_f''/P_f' = 1 + 3s' - 3s'^2/2 \quad (11)$$

$$T_f''/T_f' = 1 + s' \quad (12)$$

$$-T_{\text{in}}''/T_{\text{out}}' = -T_L''/T_L' + 2P_s'/P_L' \quad (13)$$

approximately, where P_f'/P_L' is the motor per unit friction loss.

The ratio of the power factors is

$$\cos\theta_1''/\cos\theta_1' = 1 + 2\tan\theta_1' \sin\theta_1' \times (n - \cos\theta_0)\ (1 + 6n)\ (I_{o0}/I_1') - 4n\tan\theta_1' \quad (14)$$

$$n = \tan\eta = 0.9\ R_1/X_c, \text{ approximately} \quad (15)$$

θ_0 is the angle of lag of the magnetizing current when the machine is being driven synchronously. It can be computed from the no-load current and the core loss in the primary only (synchronous core loss).

$$\cos\theta_0 = P_c/\sqrt{3}\ V\ I_m \quad (16)$$

The efficiency is essentially unchanged.

$$(\text{eff}'') - (\text{eff}') = (1 - \text{eff}')(\text{eff}')4s' - (1 - \text{eff}') \times P_2''/P_{\text{in}}' - (1 - \text{eff}' - 4\cos^2\theta_1' P_s'/P_{\text{in}}' - 12I_{o0}^2R_1\cos\theta_1''/P_{\text{in}}')P_1'/P_{\text{in}}' + (1 - \text{eff}')(3 + 4P_s'/P_L' - 4s')P_s'/P_{\text{in}}' \quad (17)$$

The generator output is slightly greater than the motor output.

$$P_{\text{out}}'' = (1 + 4s')P_{\text{out}}' - 0.35(1 + 2s)P_h', \text{ approximately} \quad (18)$$

Equivalent Circuit Constants

The constants of the exact equivalent circuit in Figure 1 can be obtained from several tests. The first is the conventional blocked rotor test. The equivalent 60-cycle resistance is the slope of the power versus current squared curve. P_e is the input power per phase corrected for the core loss at the reduced voltage.

$$(R_1 + R_2)_{(60\ \text{eqs})} = R_e = P_e/I_e^2$$

$$R_{1(60)} = 1.18R_{1(\text{dc})} \quad (19)$$

$$R_{2(\text{dc})} = P_e/1.18\ I_e^2 - R_{1(\text{dc})} \quad (20)$$

The circuit in Figure 1 has the same circle diagram of current that it would have if the stray load branch were omitted. The only difference is that the actual slip scale is not linear, and the torque and output power are reduced. The winding impedance should be taken for the value of current which makes the circle diagram best fit full load conditions, as is usually done. The total winding impedance is the slope of the voltage versus current curve. The winding impedance diminishes for higher currents. A good compromise is the extrapolated short circuit impedance for 70 per cent voltage.

$$jX_1 = jX_2 = (\mathbf{Z}_e - R_e)/2, \text{ vectorially}$$

The second test is the measurement of primary core loss at synchronous speed, while the friction and windage is supplied by a small d-c motor on the shaft. The measured values will be V_T, I_{o0}, and $P_c + I_{o0}^2R_1$. From these can be calculated the middle branch constants.

$$V_0 = V_T - I_{o0}\mathbf{Z}_1, \text{ vectorially}$$

$$G_c = P_c/V_0^2$$

$$Y_c = G_c + jB_c = I_{o0}/V_0$$

If it is not possible to measure the losses at synchronous speed, the conventional no-load test at variable voltage can be used. A plot of power input minus the primary copper loss versus the square of the voltage will give the friction and windage loss when extrapolated to zero voltage. The stray load loss is negligible and the increase in primary current magnitude due to the load component is small. However, the angle of the primary current has been changed, and G_c must be computed from $P_c = P_{\text{in}} - P_f - I_{o0}^2R_1$ and not from vector values of the voltage and current.

The stray load loss is due almost entirely to tooth-speed losses, which are proportional to the motor speed squared, and the stator current squared.[3]

$$P_s = R_s(1 - s)^2I_1^2$$

$$P_s \cong R_s(1 - s)^2V_g^2[1/(R_2/s)^2 + X_2^2) + (G_e^2 + B_e^2))] \quad (21)$$

It would at first appear that a stray load conductance G_{sm} could be connected across the magnetizing branch in the equivalent circuit. This would have the value

$$G_{sm} = R_s(1 - s)^2[(G_e^2 + B_e^2) + 1/((R_2/s)^2 + X_2^2)$$

or

$$G_{sm} = R_s(G_e^2 + B_e^2 + s^2/R_2^2)(1 - s)^2$$

approximately at small values of slip.

The stray load power is actually absorbed in the rotor, and there should be a component of rotor current to supply it. In the equivalent circuit, therefore, this branch should appear in parallel with the load, as in Figure 1. The current in equation 21 can be divided into load current and magnetizing current components.

$$P_s = R_s(1 - s)^2(\overrightarrow{V_L(G_L + G_S)} + \overrightarrow{V_g Y_e})^2 \quad (22)$$

On reverse rotation tests, these current vectors are nearly in phase, and can be added arithmetically. From light to full-load, the two current vectors are practically at right angles to each other. The current through G_s is only a few per cent of that through G_L at full-load, and is only a few per cent of that through Y_e at light load, so it can be neglected.

$$P_s \cong R_s(1 - s)^2V_L^2[(s/R_2(1 - s))^2 + Y_e^2], \text{ for small slips} \quad (23)$$

Figure 3 (left). Circuits to use for a superposition solution for the currents in figure 1

Figure 5 (right). Vector diagram of the load-current components

Small detail has been greatly exaggerated. Primed letters are for full-load motor action. Double-primed letters are for full-load generator action. The vector designations are the same as in Figure 3. I_1 is the line current and θ_1 is terminal power-factor angle

If this loss is represented by a conductance in parallel with the load, it would have the value

$$G_s = R_s(1-s)^2[(s/R_s(1-s))^2 + Y_c^2] \qquad (42)$$

Define a new constant, $G_4 = R_s Y_c^2$, then $G_s = G_4((1-s)^2 + s^2/Y_c^2R_s^2)$.

For a motor with 25 per cent no-load current and 2 per cent rotor loss, the last term at full-load might have a value around 36, which is large compared to one. It would be more convenient to lump this term with the constant, so that the second factor is only a correction term for changes in speed. If

$$G_3 = G_4/Y_c^2R_s^2 = R_4/R_s^2$$

then

$$G_s \cong G_3s^2 + G_4 = G_3s^2(1+Y_c^2R_s^2/s^2) \qquad (25)$$

$$G_s = G_3s^2, \text{ near full-load} \qquad (26)$$

Reverse Rotation Test

The stray load loss can be determined from a full-speed reverse rotation test.[3] The measured values would be the terminal voltage and current, V_d and I_d, and the electrical and mechanical power inputs, P_d and P_m. I_{oa} from the no-load test is needed corresponding to the voltage V_d.

$$I_{1b} = I_d - I_{oa}$$

$$I_{ob} = I_{1b}Z_1Y_c$$

$$I_2 = I_{1b}(1+Z_1/Y_c)$$

$$V_L = V_d - I_dZ_1 - I_2Z_2$$

This test gives an independent value for the rotor resistance at 120 cycles.

$$G_L = -2G_3 = -2/R_2 = -P_L/V_L^2$$

This value of R_2 with the 60-cycle value can be used to plot a curve from which the d-c rotor resistance may be read. These two values also can be used to determine the increase in resistance with frequency for the test machine.

The stray load loss is equal to the sum of the input powers minus the known losses. The stray load is large, and therefore, easily computed without error. The electric power component of the stray load loss is

$$P_g = P_d - I_d^2R_1 - (V_d - I_dZ_1)^2\,G_c - I_2^2R_2$$

The mechanical power component of the stray load loss is $P_L = P_M - P_{friction}$. The sum is

$$P_g + P_L = (I_{ob}+I_{1b})^2\,R_s = (I_{ob}+I_{1b})^2\,G_3R_s^2$$

Solve for (G_3) using R_2 measured at 120 cycles.

The construction of circle diagrams and computations based on the circuit of Figure 1 can be simplified by a transformation to the two circuits of Figure 3.[5] The load currents can then be obtained by the superposition of the equivalent currents.

Figure 4. Simplifications of the load-component circuit in Figure 3

Induction Motor Calculations

The induction motor current calculation could be simplified by a transformation of the second circuit in Figure 3 to the circuit shown in Figure 4. This does not introduce any significant error because I_{ob} is only a few per cent of rated current, and the error is only a small fraction of this. For a slip s

$$I_2 = V_o/(1/(Y_c+Y_c/2)+(1/(G_s+G_L)) \quad \text{approximately}$$

If the exact circuit of Figure 3 is used

$$I_2 = V_o/(1/(Y_1+Y_c)+1/(G_s+G_L)+Z_1) \quad \text{exactly} \qquad (27)$$

$$I_1 = I_{oa} + I_2Z_s/(Z_c+Z_1) \qquad (28)$$

$$I_s = I_{oa} - I_2Z_1/(Z_c+Z_1) \qquad (29)$$

$$P_{1_{input}} = V_T.I_1 \qquad (30)$$

$$P_1 = I_1^2R_1$$

$$P_2 = I_2^2R_2$$

$$P_c = I_s^2G_c/Y_c^2 \qquad (31)$$

$$P_s = I_2^2G_s/((G_s+G_L)^2 \qquad (32)$$

$$P_{output} = I_2^2G_L/(G_s+G_L)^2 - T_{friction}(1-s) \qquad (33)$$

$$T_{output} = I_2^2G_L/(G_s+G_L)^2(1-s) - T_{friction} \qquad (34)$$

The air gap torque can be separated into two components

$$T = P_sG_L/(G_s+G_L)s - P_s/(1-s) \qquad (35)$$

The first is the slip-frequency torque produced by the rotor resistance loss. It is reduced slightly by the ratio of the useful G_L to the total rotor G. The second term is the stray-load torque, which is associated with the actual rotor speed,

and not with the slip speed. It is negative because it acts as a magnetic drag on the rotor, and therefore it is similar to a friction torque.

Induction Generator Calculations

Complete induction generator characteristics can be computed from the above motor formulas for negative slips. The factors for rerating a motor as a generator also can be obtained in the same manner. In the derivations which follow, primed figures will refer to motor values, and double-primed figures to the equivalent generator values for the same rated rotor current.

$$I_2'' = I_2'$$
$$I_{1b}'' = I_{1b}'$$
$$I_{0b}'' = I_{0b}'$$

The change in slip can be computed from the rotor impedance.

$$V_0 = I_2'(Z_2 + 1/(Y_1 + Y_c) + 1/(G_s' + G_L'))$$

The real part of this impedance must have the same magnitude but reversed sign, when the machine is operating as a generator.

$$R = (G_c + R_1/Z_1^2)/((G_c + R_1/Z_1^2)^2 + (B_c - X_1/(Z_1^2))^2) + R_2 + 1/G'$$

The sum of the first two terms can be called R_c. This may be simplified by assuming typical values for R_1, X_1, G_c, and B_c, and eliminating all but the significant ratios.

$$R_c = R_1(1 - X_1/X_c) + R_2, \text{ approximately}$$
$$R = R_c + R_2 + 1/G'$$
$$R = R_c + 1/(G_2 s^2 + G_2 s'), \text{ as a motor}$$
$$-R = R_c + 1/(G_2 s''^2 + G_2 s''), \text{ as a generator}$$

It is desired to solve for the ratio of the slips from these two equations by eliminating the unknown R. To facilitate it, let $-s''/s' = k$, and solve for an approximation for $R_c G_L$, from the sum of the two equations.

$$2R_c G_L = (1 + R_1(1 - X_1/X_c)/R_c)s'(1 + k)/(1 - s')$$

$$2R_c G_L = 2s'(1 + k) \text{ approximately}$$

Eliminating R, and substituting the ratio of powers for conductances

$$k(1 - s'(1 + k) + (1 + 3s'(1 + k))P_s'/P_L' = (1 + P_s'/P_L')(1 - 2R_c G_L(1 + P_s'/P_L')) \quad (36)$$

This can be simplified by solving for k by dividing the right side by the left side

$$-s''/s' = k = 1 - s'(1 + k)(1 - 4s' + 4P_s'/P_L') - (P_s'/P_L')^2$$

For low slip motors, $(1 + k)$ is almost 2, so that

$$-s''/s' = 1 - 2s', \text{ approximately.}$$

Substituting $(1 + k) = 2(1 - s')$, which is true for motors with rotor resistance equal to stator plus line resistance, and discarding high order terms

$$-s''/s' = 1 - 2s'(1 - 5s' - 4s'^2 + 4(P_s'/P_L')) - (P_s'/P_L')^2 \quad (37)$$

$$-s''/s' = 1 - 2s'(1 + 4P_s'/P_L' - 5s'), \text{ approximately} \quad (38)$$

Equation 37 holds for large low slip motors with equal equivalent stator and rotor resistances. A more exact expression is given in equation 64. It shows that the approximate equation 38 above gives values of generator slip which are too high. A much better approximation is

$$-s''/s' = 1 - s'(2 + 9P_s'/P_L - 6s') \quad (7)$$

The ratio of the speeds is

$$(1 - s'')/(1 - s') = 1 + 2s' - 2s'^2$$

Figure 5 shows the vector relationships of the load current components. I_2' and I_2'' are each at an angle θ_2 with the voltage V_b. I_{1b}' and I_{1b}'' are equal in magnitude, but their phase angles are $(\theta_2 - n)$ and $(\theta_2 + n)$. The angle n also is the angle of lead of V_0 ahead of V_T.

$$V_0/V_T = Z_c/(Z_1 + Z_c) = M/n$$
$$I_{1b}/I_2 = Z_c/(Z_1 + Z_c) = 1/(1 + Z_1 Y_c) = M/n$$

M is approximately equal to one minus the no-load per unit primary reactance drop.

$$I_1'/\theta_1' = I_{1b}'/-\theta_2 + n + I_{0a}/-\theta_0$$
$$I_1''/\theta_1'' = I_{1b}''/180 + \theta_2 + n + I_{0a}/-\theta_0$$

If all the current vectors are rotated n degrees clockwise I_{1b}' and I_{1b}'' will occupy symmetrical positions and the cosines of their angles will be the same. The out-of-phase component of I_{0a} will be essentially unchanged. Therefore, the projections of I_1' and I_1'' on a perpendicular to yz will be equal. The difference between I_1' and I_1'' will be cos θ times the in-phase differences. The projections on yz will be

$$I_1' \cos(\theta_1' + 2n) = I_{1b}' \cos(\theta_2) + I_{0a} \cos(\theta_0 + n) \quad (39)$$

$$I_1'' \cos(\theta_1'' - 2n) = I_{1b}'' \cos\theta_2 - I_{0a} \cos(\theta_1 + n) \quad (40)$$

$$I_1' - I_1'' = 2I_{0a} \cos(\theta_0 + n) \cos(\theta_1' + 2n) \quad (41)$$

This formula gives the reduction in line current for shifting from motor to generator full load. It is fairly accurate even for small machines. It is not important for the value of n to be known precisely.

$$n = \tan^{-1} X_c/R_c - \tan^{-1}(X_1 + X_c)/R_1 + R_c)$$

$$\tan n = \frac{X_c/R_c - (X_1 + X_c)/(R_1 + R_c)}{1 + X_c(X_1 + X_c)/R_c(R_1 + R_c)}$$

$$n = \tan n = \sin n = 0.87\ R_1/X_c \text{ radians, approximately} \quad (15)$$

$$I_1''/I_1' = 1 - 2I_{0a} \cos(\theta_0 + n) \cos(\theta_1' + 2n)/I_1'$$

This equation also is exact and contains no approximations. However, for many cases, an equation in different form is preferable

$$I_1''/I_1' = 1 - 2I_{0a}(\cos\theta_0 \cos\theta_1' - \sin n (\cos\theta_1' + 2\cos\theta_0))/I_1'$$

If sin n were about equal to cos θ_0, there would be no change in the primary current.

$$\cos\theta_1 = G_c/Z_c$$

$$I_1''/I_1' = 1 - 2\left(\frac{V_0 I_{0a} \cos\theta_0 \cos\theta_1'}{I_1' V_0} - \frac{I_{0a} R_1}{I_1' X_c}\right)$$

$$I_1''/I_1' = 1 - 2(P_c \cos\theta_1' - 3I_{0a}^2 R_1)/VA, \text{ approximately} \quad (3)$$

The per-unit generator terminal current is less than the motor current by twice the ratio of the difference between the no-load primary core loss times the full-load power factor minus the no-load primary copper loss to the machine volt-ampere rating. This value is less than the percentage core loss, and can even be zero if the primary resistance is quite large.

There is no simple equation for the ratio of the power factors. In Figure 5, V_T is the terminal voltage for both motor and generator action, and V_0 is the no-load internal voltage. The internal voltage with load is shifted in phase considerably. The actual magnetizing current with load is

$$I_m' = I_{0a} - I_{0b}' \quad (42)$$

The generated voltage is

$$V_g' = (I_{0a} - I_{0b}')Z_c \quad (43)$$

The difference between $(\theta_1' + 2n)$ and $(\theta_1'' - 2n)$ is very small.

$$d\alpha = -\sin^2\alpha d \cot\alpha$$

$$\theta_1'' - 4n - \theta_1' = \sin^2(\theta_1' + 2n) 2I_{0a} \cos((\theta_0 + n)/I_1' \sin(\theta_1' + 2n)$$

$$\theta_1'' - \theta_1' = 4n + 2(\sin\theta_1' + 2n \cos\theta_1')I_{0a}/I_1' \quad (44)$$

The above is the difference in power factor angle.

$$\cos\theta_1'' = \cos\theta_1' \cos(\theta_1'' - \theta_1') - \sin\theta_1' \times \sin(\theta_1'' - \theta_1')$$

$$\cos\theta_1''/\cos\theta_1' = 1 - 4n \tan(2I_{0a} \sin\theta'/I_1') - \tan\theta_1' \tan(2I_{0a} \sin\theta'/I_1')$$

$$\cos\theta_1''/\cos\theta_1' = 1 - (4n + \tan\theta_1') \tan(2I_{0a} \times \sin\theta_1'/I_1') \quad (45)$$

In actual computations, this equation appears to be quite inaccurate.

There is another method of obtaining the ratio of the power factors from equations 39 and 40.

$$\frac{\cos(\theta_1'' - 2n)}{\cos(\theta_1' + 2n)} = \frac{1 - 2I_{0a} \cos(\theta_0 + n)/I_{1b}'' \cos\theta_2}{1 - 2I_{0a} \cos(\theta_0 + n) \cos \times (\theta_1' + 2n)/I_1'}$$

Substituting $I_{1b} \cos\theta_2$ for $I_1' \cos(\theta_1' + 2n)$, and simplifying,

$$\cos\theta_1''/\cos\theta_1'' = 1-4s\tan\theta_1' - 2(I_{0a}/I_1')\times(\cos\theta_0 - n)(1+6n)\sin\theta_1'\tan\theta_1' \quad (14)$$

This equation is accurate to better than 20 per cent even for nonconventional motors.

The change in the magnetizing current is important in considering the core loss.

$$\mathbf{I}_{0b}/\mathbf{I}_1 = \mathbf{Z}_1/(\mathbf{Z}_1+\mathbf{Z}_2) = Z_1M/\underline{n}/Z_c = K/\underline{\beta}$$

$$\mathbf{I}_{0b}/\mathbf{I}_2 = 1.01X_1/X_2 - j.88R_1/X_2 = K/\underline{\beta},$$

approximately

$$\beta = \tan^{-1}(-0.87R_1/X_1) \quad (46)$$

$$K = Z_1/X_c \quad (47)$$

From Figure 5

$$I_c' = I_{0a} - (I_2Z_1/X_c)\sin(\theta_2+\beta) \quad (48)$$

$$\frac{I_c''}{I_c'} = \frac{1+(I_2Z_1/I_{0a}X_c)\sin(\beta-\theta_1)}{1-(I_2Z_1/I_{0a}X_c)\sin(\theta_2+\beta)}$$

$$I_e''/I_c'' = 1+2I_1'R_1\cos\theta_1'/V_0 \quad (49)$$

This says that when changing from motor to generator action, the magnetizing current increases in per unit values two times the power factor times the per-unit primary resistance. The actual generated voltage is proportional to the magnetizing current.

$$V_g''/V_g' = 1+2I_1'R_1\cos\theta_1'/V_0 \quad (50)$$

The primary core loss is proportional to the square of the generated voltage.

$$P_c''/P_c' = 1+4I_1'R_1\cos\theta_1'/V_0 \quad (51)$$

The primary copper loss is proportional to the square of the terminal current. Using equation 3,

$$P_1''/P_1' = 1-4(P_c\cos\theta_1 - 3I_{0a}^2R_1)/VA \quad (52)$$

If greater accuracy is required, equation 41 could be used, but its form is not as convenient.

The secondary copper loss is constant.

$$P_2''/P_2' = 1$$

The stray load loss is proportional to the speed squared and to the stator current squared

$$P_s''/P_s' = (1+2s')^2(1-4(P_c\cos\theta_1 - 3I_{0a}^2R_1)/VA)$$

$$P_s''/P_s' = 1+4s'-4(P_c\cos\theta_1 - 3I_{0a}^2R_1)/VA \quad (53)$$

This last equation is easy to visualize. The per-unit change in loss is $4s$ due to a speed change of $2s$. The last term is due to the change in primary current, which is mainly influenced by the core loss.

The variation in friction loss is

$$P_f''/P_f' = (1-s'')^{3/2}/(1-s')^{3/2} = 1+3s' - 3s'^2/2 \quad (11)$$

The power associated with G_L is the mechanical power input in excess of friction losses

$$P_L'' = I_2^2G_L''/(G_L''+G_s'')^2$$

Setting up the ratio of the powers

$$\frac{-P_L''}{P_L'} = \frac{G_L'(1+G_s'/G_L')^2}{G_L''(1+G_s''/G_L'')^2}$$

Substituting the values of G_L and G_s and eliminating the ratio of the slips between this equation and equation 36 will give

$$-P_L''/P_L' = (2-k)[1+s'(1+k)\{1+[1+k(1-3s'(1+k))]P_s'/P_L'\}^2]$$

$$-P_L''/P_L' = 1+2s'(2+s'+24(P_s'/P_L')^2)+4(1+(P_s'/P_L')-2(P_s'/P_L')^2-14s'^2)P_s'/P_L' \quad (55)$$

$$-P_L''/P_L' = 1+4s'+4P_s'/P_L', \text{ approximately} \quad (56)$$

Equation 55 has no approximations. It gives values of P_L'' which are too high, however. Equation 56 neglects the higher order terms, and is sufficient for high-efficiency low-slip machines. It gives values of P_L'' which are too low.

The machine handles more power as a generator than as a motor. Even if the rotor current is the rated value, the air-gap power will be increased due to the higher voltage, and the input power is even greater than this by the rotor losses. The internal torque in synchronous watts is

$$T = P_L/(1-s)$$

Substituting equations 55 and 7 in the above, and discarding third order terms

$$-T''/T' = 1+2s'(1+4s')+4(1+P_s'/P_L')P_s'/P_L' \quad (57)$$

$$-T''/T' = 1+2s'+4P_s'/P_L', \text{ approximately} \quad (10)$$

This gives generator values which are low.

The losses now may be tabulated.

Motor Losses	Generator Losses	From Equation
P_f'	$(1+3s')P_f'$	(11)
P_s'	$(1+4s'-4(P_c\cos\theta_1 - 3I_{0a}^2R_1)/VA)$	(53)
P_2'	P_2'	
P_1'	$(1+4I_{0a}^2R_1/VA - 4P_c\cos\theta_1'/VA)P_1'$	(52)
P_c'	$(1+4P_1'\cos\theta_1'/VA)P_c$	(51)
Sum $= P_h'$	Sum $= P_h''$	(58)

The sum of the losses can be simplified by assuming that typical design values of per unit R_1, $\cos\theta'$, and I_{0a} are functions of the slip, so that roughly

$$P_h'' = (1+3s')P_f'+(1+4s')P_s'+P_2'+(1+80s'^2)P_1'+P_c' \quad (9)$$

To illustrate the significance of these figures, the temperature rise can be computed. It is sufficiently accurate at this point to assume for a class A motor the following distribution of losses: 40 per cent of the total losses for P_1, 30 per cent for P_2, 10 per cent for P_s, 12 per cent for P_2, and 8 per cent for P_f.

The ratio of the total losses and therefore the heating as computed by equation 9 is $H''/H' = (1+1.7s')$. The temperature rise is $T''/T' = (1+1.7s')/(1+2s') = (1-0.3s')$. The difference of $0.3s'$ is less than a degree. Therefore a class A motor can be operated as a generator at rated rotor current and a terminal current of $1-2(P_c\cos\theta_1'-I_{0a}^2R_1)/VA$ times the rated stator motor current.

The generator output will be greater than the motor output.

$$P_{out}' = P_L' - P_f'$$

$$P_{in}'' = P_L'' + P_f''$$

$$P_{out}'' = P_{in}'' - P_h'' = P_L'' + P_f'' - P_h''$$

$$P_L'' = (1+4s'4s'+2s'^2)P_L'+(1+P_s'/P_L')4P_s' \text{ (From equations 11, 55, and 9)}$$

$$P_{in}'' = (1+4s'+2s'^2)P_{out}'+(2+7s')P_f'+(1+P_s'/P_L')4P_s'$$

$$P_{in}'' = P_{in}'+(2+s')2s'P_{out}'+(1+7s')P_f'+(3+4P_s'/P_L')P_s'-P_c'-P_1'-P_2' \quad (59)$$

$$P_{out}'' = (1+4s'+2s'^2)P_{out}'+(1+4s')P_f'+(3+4P_s'/P_L'-4s')P_s'-P_c'-P_2'-(1+80s'^2)P_1' \quad (60)$$

Assuming the same distribution of losses as before, the approximate new power rating is

$$P_{out}'' = (1+4.04s')P_{out}'-0.35(1+2s')P_2' \quad (18)$$

A motor with 94 per cent efficiency at 2 per cent slip would deliver about 6 per cent more power as a generator than its motor rating. A motor with 70 per cent efficiency at 10 per cent slip would deliver 22 per cent more power as a generator.

The ratio of the per-unit losses is

$$(1-\text{eff}'')/(1-\text{eff}') = P_h''P_{in}'/P_{in}''P_h'$$

$$P_h'' = P_h'+3s'P_f'+4s'P_s'+(80s'^2)P_1' \quad (61)$$

$$(\text{eff}'')-(\text{eff}') = (1-\text{eff}')(\text{eff}')4s+(1-\text{eff}'-s')P_f'/P_{in}'+(1-\text{eff}')(3+4P_s'/P_L'-4s')P_s'/P_{in}'-(1-\text{eff}')P_c'/P_{in}'-(1-\text{eff}')P_2'/P_{in}'-P_c'-P_2'-(1+80s'^2)P_1' \quad (62)$$

The relative magnitudes of these terms and the change in efficiency can be computed for the previously assumed distribution of losses, 85 per cent efficiency, and 3 per cent slip.

$$(\text{eff}'')-(\text{eff}') = (1-\text{eff}')(0.12\times0.85+0.08\times0.12+0.12\times0.468-0.1\times0.15$$
$$= 0.15(0.102+0.010+0.0561-0.015-0.045-0.032) = +0.011$$

This increase in efficiency of 1 per cent is a little more than the computed increase in temperature rise. Not only is it quite

Table I

	Test Motor	Test Generator	Exact	Calculated Generator Equation	Approximate	Equation
I_1	30 amperes	28.7 amperes	28.55 amperes	41	27.7 amperes	3
V_1	113 volts	118 volts	118 volts assumed			
P_{in}	5,000 watts	6,590 watts	6,710 watts	53	6,460 watts	56
			6,821 watts	59		
P_h	1,900 watts	2,180 watts	2,300 watts	58	2,213 watts	61
P_{out}	3,100	4,410	4,410 watts	55–58	4,607 watts	60
			4,521	59–58	4,247 watts	56–61
eff	0.62	0.67	0.658	55–58	0.75	63
					0.756	17
Slip	0.0666	0.0433	0.0425	64	0.0425	7
			0.0553	37	0.0563	38
Speed	1,120 rpm	1,252 rpm	1,251 rpm	64	1,251	7
			1,266.5 rpm	37	1,267.5 rpm	38
$\cos\theta$ = p.f.	0.84	0.752	0.758	41–55–59	0.621	2
			0.768	14	0.494	45

small, but it is due to the differences between several second-order effects. Third-order terms have been neglected, when they were not significantly large, so that the accuracy of this efficiency difference is poor. An examination of the relative magnitudes in the preceding equation shows that the first term is the most significant and that the sum of the second and fourth terms is essentially zero. It also should be noted that the last term, which is fairly large, is derived from equation 9 in which $80s'^2$ was substituted as an approximation for $4\cos\theta_1' P_s'/VA + 12\, I_{0a}^2 R_L/VA$. Replacing the exact value in equation 62

$$(\text{eff}'') - (\text{eff}') = (1-\text{eff}')(\text{eff}')4s'^2 + (1-\text{eff}'-s')P_f'/P_{in}' + (1-\text{eff}')(3+4P_s'/P_L'-4s')P_s'/P_{in}' - (1-\text{eff}')P_c'/P_{in}' - (1-\text{eff}')P_s'/P_{in}' - (1-\text{eff}' - 4\cos^2\theta_1' P_s'/P_{in}' - 12 I_{0a}^2 R_1 \cos\times \theta_1'/P_{in}')P_1'/P_{in}' \quad (63)$$

If the terms with friction and core loss are omitted this becomes equation 17 which has been previously stated. Both equations 63 and 17 give values for the change in efficiency for small machines which are much too large.

The increase in efficiency is usually small and will be greatest in machines with a high ratio of slip to per-unit rotor loss (high percentage stray load loss).

The best over-all test of this method and these formulas is a comparison between calculated generator characteristics and actuality.[7] For a small low-efficiency high-slip motor, the discrepancies should be large when the approximate formulas are used. Since many of the approximations are not valid for these conditions, this should make a good test to determine the limits of the extent of the applicability of these formulas. Table I shows these results quite strikingly. The more exact expressions for power and efficiency were fairly reliable, while the approximate expressions for power factor were quite poor. The computed speed using equation 37 was in error by 15 rpm, or over 1 per cent. This was due to the fact that in equation 37, the substitution $2R_sG_L = 4s$ was used.

For this machine, $2R_sG_L = 4.95s'$. Making this substitution in equation 36, one can derive a slip equation accurate for machines with rotor resistance different than stator plus line resistance.

$$-s''/s' = 1 - 2s'(1 + 2P_s'/P_L' - s' + (P_s'/P_L' - 2s')(1 + 0.95R_1/R_2)) - (P_s'/P_L')^2 \quad (64)$$

A simplification of this is

$$-s''/s' = 1 - s'(2 + 9P_s'/P_L' - 6s') \quad (7)$$

This equation was given previously without derivation. If it is used to compute the slip for the test machine, it yields

$s'' = 0.0426$, and $N'' = 1251$ rpm, only one rpm in error

The terminal voltage of the machine was a variable due to the regulation of the power supply. This was represented in the computations by a line resistance of 0.074 ohm per phase added to the primary resistance of 0.126 ohm per phase. The no-load voltage was 116 volts, and this was used to compute the V_0 in equations 3, 51, 52, and 53. The motor losses were 400 watts each for friction and core, 340 watts each for stator and copper losses, and 420 watts stray load loss.

Quick and Accurate Production Testing on Large D-C Apparatus

M. J. BALDWIN
MEMBER AIEE

H. D. BARNHART
ASSOCIATE AIEE

THE testing method described was devised for the purpose of shortening the time and avoiding some of the inaccuracies of the customary methods of making routine production tests on large d-c machines. It is based on the use of the reluctance of the flux paths of the machine to indicate their uniformity, and involves a procedure in which the machine under test is driven as a generator without load. Results obtained during many months of factory use have amply demonstrated the superiority of this method, as a quick check on standard production machines.

Developmental Versus Commercial Tests

After a new type of machine is tested and all adjustments have been made from a design standpoint, the problem is then one of making all succeeding machines like the one just tested.

Load tests provide an adequate means of determining that no parts are rubbing, that the commutator is reasonably smooth, and that the bearings are free and properly lubricated. Readings of speed and commutation are customary and serve to indicate, in a rough way, whether a machine is working as it should. Frequently the service application of the machine is such that this is an adequate check. As the specific output of motors and generators is increased, more accurate gauges of speed and commutation adjustment are needed. With ordinary load testing, a good test on either of these points involves the use of a controlled condition of brush fit that is generally known as a full face load fit.

A full face load fit is difficult to obtain. The brushes must first be sanded and seated to what is known as a seater fit. With a fit of this kind, the brush is approximately, but not accurately, fitted to the commutator. The process of applying the seater changes the friction between the brush and commutator. This friction also varies with the amount of oxide film and brush deposit on the commutator. As the friction varies, the brush position varies microscopically; and with each brush position there is a change in commutation. It is difficult to obtain consistent test results even during developmental testing. To carry out the same tests for production machines would involve so much testing time that it is not practical.

The method of testing here described is intended to indicate the accuracy of speed and commutation adjustment without the use of carefully fitted brushes.

Development of the Method

A method used in testing some 300 machines during the war pointed the way to the development of a short commercial test for production machines. It is well known that the uniformity of the magnetic circuit in a given machine may be determined by checking its reluctance. This method has had wide commercial application for indicating the uniformity of the exciting flux paths variables within acceptable limits. In the case of the 300 machines, it also was used with great success to indicate the uniformity of the commutating flux path.

The experience gained in these first tests made it possible to build special equipment for the development of this method of indicating the commutation to be expected so that it could be applied to the commercial testing of traction motors on a high production basis. This application has made possible a complete revamping of the commercial test routine with numerous beneficial results.

Test Schedule

Fundamentally the schedule followed consists of four simple tests plus the customary overspeed, high-potential, and hot impedance tests.

1. A no-load saturation curve is taken with the main poles excited and the armature driven at a fixed speed. This curve is used to indicate uniformity of main flux circuit reluctance including the accuracy of the main pole air gaps. This, in turn, gives an indication of the full load speed.

2. A no-load saturation curve is taken with only the commutating poles excited and the armature driven at a fixed speed. This curve is used to indicate uniformity of commutating flux circuit reluctance including the accuracy of the commutating pole air gap. This, in turn, gives an indication of the grade of commutation to be expected.

3. The machine is operated for heating up and bearing test, at load speed with load current in the armature and commutating field, but with no main field excitation. Incidentally, variations in the power necessary to drive the machine in this test have been found to be an indication of the symmetry of the brush holders, the commutating poles, and the main poles.

4. High-voltage run (45 volts per bar) is made driving the hot armature at about 10 per cent overspeed.

Figure 2. Pneumatic pencils and fixture used with compensation bridge

The test described is in no way a substitute for conventional developmental load testing which, as ever, is required in making adjustments on the first machine built. Neither does it eliminate the periodic load test as a check on machine quality. The new method, however, serves to indicate that the succeeding machines are like the first one, not only in that they will run, but also in that the speed and commutation will be like the first one tested. This is the factor upon which an accurate check must be made in the machines where close commutation adjustment is essential to successful operation.

Use of the Compensation Bridge

Certain refinements have been made in the method to read volts and amperes when checking commutation in test 2 previously mentioned.

The compensation bridge circuit shown in Figure 1 was developed for reading a ratio of volts per ampere directly. The circuits of this bridge (known generally as the *CP* bridge) are arranged so that the potential induced in the armature is picked up by special pencils bearing on the commutator and impressed across the resistance R_1 and R_2. The potential drop across a current shunt in the commutating field circuit is impressed on the terminals marked "shunt". By adjusting the value of R_2 until the voltage drop across R_1 is equal to that across the shunt, the flow of current in the galvanometer can be brought to zero. In this way the *CP* bridge can be used to indicate volts per ampere in terms of the value of the adjustment of R_2. The bridge offers a special advantage over the alternative method of taking simultaneous readings of pencil volts and commutating field amperes. In the normal operating range of a properly designed commutating pole flux circuit, the reluctance is essentially constant. With this constant reluctance, the bridge readings will be constant, even with small error in the setting of the commutating field current.

From these considerations it is evident that the bridge can be used to indicate the reluctance of the commutating flux path. It is only necessary to calibrate the resistance dial with a properly compensated machine in order to use the bridge to indicate the proper adjustment of the commutating poles. In the case of an overcompensated machine (too much commutating pole flux) the pencil voltage will be greater and, therefore, a higher resistance setting will be required to balance the bridge. For an undercompensated machine a lower setting will be required. The bridge circuit as now used for commercial tests is essentially the same as Figure 1, except that two protective resistors have been added, and a self-balancing bridge has been substituted for the galvanometer.

A special pneumatic pencil fixture, shown in Figure 2, has been developed for use in this application. Pencil lead operating under approximately 90 pounds per square inch pressure has been found best for the purpose. The lead should be at least 0.020 inch larger in diameter than the width of the undercut mica groove between segments. If the pencils are spaced far enough apart to include all the segments between which any appreciable amount of voltage is generated by commutating pole flux, it will not be necessary to provide any high degree of accuracy in the supporting fixture either as to spacing or location.

Speed Control

As pointed out previously, the setting of the commutating field current is not of critical importance. This then leaves only the accurate measurement of speed as the major consideration in the *CP* bridge readings.

The method used to indicate speed employs an oscilloscope to compare the frequency of an a-c tachometer with the frequency of a standard 250-cycle tuning fork. A phase-shifting network is used to obtain a second 250-cycle frequency with a 90-degree voltage lag with respect to the original. These two are then used for

Figure 3. View of test area showing test table, motors in test stands, and tracks and turntable for motor conveying dolly

Figure 7. Test motor on dolly ready for positioning in stand, showing adjustable nose support in foreground

vertical and horizontal input to obtain a circle trace on the oscilloscope. The tachometer frequency is applied to the Z-axis of the oscilloscope to modulate the circle trace, blanking out a small segment of the circle. When the two frequencies are different, the blanked portion will revolve, but when properly synchronized the blanked out portion will appear to stand.

The tuning fork itself is of bimetallic construction, making a close approach to a zero temperature coefficient possible. The accuracy of the fork is one part in 100,000 or 0.001 per cent with a temperature coefficient of one part in 1,000,000 per centigrade degree from 0 to 60 degrees centigrade.

One tuning fork was set up in the General Electric Company Laboratory with circuit provided for comparing directly with the time check broadcast by radio station, WWV. A signal from this fork was transmitted to the test floor over the company's telephone circuits. Two other forks were made up in oscilloscope cases to form portable speed-fixed frequency standards.

With normal control of speed it requires no special skill to hold the tachometer frequency almost the same as the standard 250-cycle frequency. This constant speed is required only long enough to obtain one *CP* bridge or saturation reading at a time. The ratio of 16 cycles per revolution makes the visual indication of speed very accurate. In terms of speed 1 rpm of oscilloscope indication represents only 1/16 of an rpm of the test motor.

Figure 6. Double universal drive for test motors. Coupling guard shown with cover open

Conclusions

The method described permits the use of a much simpler mechanical set-up on the test stand. See Figures 3, 4, and 5. In the case of testing a traction motor with axle and nose suspension, a 3-point suspension type of support is used as shown in Figures 5 and 7. The driving power is transmitted by a long, double-universal, drive shaft, see Figure 6, in order to adapt the set-up to all sizes of motors. Development installation now has been in operation for about two years. In that time, it has demonstrated many advantages, both from the standpoint of quality of the results and economy of time, as indicated below:

1. The *CP* bridge substitutes for the usual time-consuming and uncertain method of observing commutation during the load run an accurate method of indicating commutation which eliminates the inaccuracies caused by a poor brush fit, commutator film, commutator roughness, or instability of the brushes in the brush holders.

2. In addition to the indication of full-load speed normally obtained, it now is possible to obtain data indicating the accuracy of the air gap and the quality of the metal portion of the main exciting flux path.

3. The power requirements are small and are independent of machine rating for a given type of machine.

4. The same meters can be used for testing a large number of machines of the similar type with the single exception of the voltmeter to read terminal voltage.

No Discussion

Transient Response of Direct-Current Dynamos

H. E. KOENIG
ASSOCIATE AIEE

Synopsis: Equations for the transient current of both the armature and field of a d-c shunt-wound machine are developed. The equations are derived from the theorem of constant flux linkages and in terms of the mutual inductance between the armature and shunt field. Methods for measuring this mutual inductance as well as other constants of the machine are developed. It is believed that the analysis can be extended to include almost any type of d-c dynamo, including the amplidyne. The results obtained from the theoretical analysis are in agreement with experimental data.

THE problem of transient analysis of both a-c and d-c machines has been of great interest to electrical engineers for several decades. During the period from 1928 to 1930 many of the problems of transient short circuits on synchronous machines were solved by R. H. Park,[1,2] R. E. Doherty and C. A. Nickle,[3,4] and others. Most of this work had been directed toward the special problem of short circuits, since it was then the problem of major importance in the field of a-c machines. Much of R. H. Park's work, however, included a general solution that could be extended to practically any type of a-c machine problem involving transient conditions.

In recent years the increased use of d-c distribution systems on ships and the use of d-c dynamos in servo systems has made necessary a more complete understanding of d-c machine transient phenomena. One of the special problems was that of finding the transient short-circuit current of d-c generators for relay co-ordination. Since 1946 considerable work has been done on this special problem by T. M. Linville and H. C. Ward, Jr.,[5,6] and G. E. Frost.[7] Briefly their analyses consist of finding a transient and a subtransient impedance similar to the transient and subtransient reactances of synchronous machines. In general, the formulas are quite similar to the well-known formulas for synchronous machines.

For the particular problems concerning short-circuit currents and torques, the analyses available give reasonably good results. However, to the author's knowledge, no general analysis is available which is applicable to the type of transient problem met in servo control systems.

In the transient analysis of d-c machines it has been found convenient to use the 2-reaction theory similar to that used in synchronous machine studies.[1] The general method of attack consists of dividing the armature current, voltage and flux linkages into the direct- and quadrature-axis components. Expressions for the direct- and quadrature-axis flux linkages of the armature and field then are derived in terms of measurable quantities of the machine. Since the armature terminal voltage is a function of the rate of change of flux linkages, a differential equation finally is obtained for the terminal voltage of the machine in terms of the field voltage and constants of the machine. The analysis that follows is for the particular case of a shunt machine with commutating poles and zero brush shift. The same approach could be extended quite conveniently, however, to the analysis of compound machines and amplidynes.

Assumptions

In practically all machine analyses it is necessary to make certain simplifying assumptions. In this analysis the following assumptions are made:

1. The machine is symmetrical about both axes.
2. The eddy current and hysteresis losses are neglected in the development of the equations, but not in the evaluation of the constants of the machine.
3. The brush axis does not shift with load.
4. The magnetomotive force of the short-circuited winding undergoing commutation is negligible.
5. The coefficients of the equations are considered as constants over a limited range of operation.

Generalized Analysis

The direct and quadrature axes are chosen as shown in Figure 1. The direct-axis current is that component of armature current which produces armature reaction along the direct axis. Likewise, the quadrature component of armature current is that component which produces armature reaction along the quadrature axis.

For zero brush shift the brush axis is in line with the quadrature axis. Under this condition almost all of the armature reaction is in quadrature with the main field or direct axis. With zero brush shift a decrease in the direct-axis flux caused by an increase in armature current is a result of saturation of the shunt-field pole tips. The saturation of the pole tips which decreases the shunt-field flux causes a voltage to be induced in the field under transient conditions. Therefore the effect of this saturation must be included in the analysis. Since this voltage induced in the field is proportional to the quadra-

The author wishes to express his gratitude to Dr. G. H. Fett of the Electrical Engineering Department, University of Illinois, who suggested the study of this problem, for his suggestions and guidance in the preparation of this manuscript, and to Professors C. A. Keener, H. N. Hayward, and J. E. Williams, also of the Electrical Engineering Department, for their suggestions and comments.

The author also acknowledges the permission granted by the Graduate College of the University of Illinois to utilize material included in a thesis submitted under the same title in partial fulfillment of the requirements for the degree of Master of Science.

Figure 1 (left). Schematic diagram of dynamo showing reference axes

Figure 4 (right). Bridge circuit for measuring the mutual inductance between the armature and shunt field. Under balanced conditions $m_2/m_1 = R_2/R_1 = \beta_2/r$

ture component of armature current, it can be represented by the product of a mutual inductance term, M_{af}', and Pi_q.

Let positive armature current in the direct axis be defined as that which produces positive armature flux linkages in the direct axis. If saturation except for that of the shunt-field pole tips is neglected, the general expression for the direct-axis armature flux linkages becomes

$$\begin{aligned}\varphi_d &= k_f I_d - (x_1 + x_d')i_d - x_d'' i_q \\ &= k_f I_d - X_d i_d - x_d'' i_q\end{aligned} \tag{1}$$

where x_d'' is an inductance term to account for the decrease in φ_d caused by the saturation of the shunt-field pole tips.

Similarly let positive armature current in the quadrature axis produce positive armature flux linkages in the quadrature axis.

Then

$$\begin{aligned}\varphi_q &= k_c I_q - (x_1 + x_q')i_q \\ &= k_c I_q - X_q i_q\end{aligned} \tag{2}$$

Since the effect of saturation of the commutating pole tips is very small, it is neglected in this expression.

The flux linkages with the field in the direct and quadrature axis are respectively

$$\gamma_d = L_f I_d + M_{af} i_d - M_{af}' i_q + M_{cf} I_q \tag{3}$$

$$\gamma_f = L_c I_q - M_{ac} i_q + M_{cf} I_d \tag{4}$$

For the special case of zero brush shift, $i_q = I_q$ = total armature current, and i_d is the short-circuit current of the coil undergoing commutation. Under this condition $M_{af} i_q$ and $X_d i_d$ are both negligible since the number of turns in the direct axis of the armature is very small.

If P is defined as the operator, d/dt, the expressions for the direct and quadrature components of armature voltage become

$$e_q = \varphi_d P\delta + P\varphi_q - P\gamma_q - i_q r_q \tag{5}$$

$$e_d = \varphi_q P\delta + P\varphi_d - i_d r_d \tag{6}$$

where $P\delta$ represents the speed of rotation of the armature. The voltage e_q is the voltage which produces i_q. In the particular case of zero brush shift, e_q is the terminal voltage of the machine.

By the proper choice of units, some of the constants of equations 1 thru 4 can be eliminated. Let the unit quantities be defined as shown in Appendix I. Equations 1 through 4 then reduce to the following

$$\varphi_d = I_d - x_d'' i_q \tag{7}$$

$$\varphi_q = k_c' i_q \tag{8}$$

$$\gamma_d = I_d - M_{(a+c)f} i_q \tag{9}$$

$$\gamma_q = L_c' i_q + M_{cf} I_d \tag{10}$$

where $k_c' = k_c - X_q$, $M_{(a+c)f} = M_{af}' - M_{af}$ and $L_c' = L_c - M_{ac}$.

Since the commutating field is connected in series with the armature it becomes convenient to choose the unit of γ_q equal to the unit of φ_d and φ_q. Equations 5 and 6 can then be written as

$$e_q = \varphi_d + P\varphi_q - P\gamma_q - i_q r_q \tag{11}$$

$$e_d = \varphi_q + P\varphi_d - i_d r_d \tag{12}$$

It now is possible to express all flux linkages in equation 11 in terms of E_d and i_q. As derived in Appendix II, the expression for the terminal voltage of the machine then becomes

$$\begin{aligned}e_q = Pk_c' i_q - P\Bigg[& L_c' i_q + \\ & \frac{M_{cf}(E_d + M_{(a+c)f} T_e P i_q)}{1 + T_e P}\Bigg] - r_q i_q + \\ & \frac{E_d + [(M_{(a+c)f} - x_d'')T_e P - x_d'']i_q}{1 + T_e P}\end{aligned} \tag{13}$$

This gives one equation with two unknowns, namely e_q and E_d. However, for any particular case one or the other would be known. For instance, in the case of a generator e_q would be known as a function of i_q.

To obtain an expression for the field current, equation 9 is substituted in equation 23 to give

$$I_d = \frac{E_d}{1 + T_e P} + \frac{M_{(a+c)f} T_e P i_q}{1 + T_e P} \tag{14}$$

It should be noted that if the armature current is zero, the first term of equation 14 represents the differential equation of the field circuit. If E_d is held constant the first term becomes E_d and the transient is given by the last term.

Prediction of Transient

For the purpose of checking the foregoing analysis, consider the problem of a sudden increase in the shunt-field voltage of a separately excited generator. The generator is driven at constant speed and is delivering power to a pure resistance load.

The transient current of the armature and field are to be found. If r_L is the load resistance, then $e_q = i_q r_L$. Substitution of $i_q r_L$ for e_q in equation 13 gives

$$i_q = \frac{E_d(1 - M_{cf}P)}{(M_{cf}M_{(a+c)f} - k_c' + L_c')T_oP^2 + [L_a' - k_c' + (r_L + r_q + x_d'' - M_{(a+c)f})T_o]P + r_L + x_d'' + r_q} \tag{15}$$

The quantity $r_q + x_d''$ is sometimes referred to as the "synchronous resistance" of the armature,[7] since it is analogous to the synchronous reactance of a synchronous machine. It represents the steady-state resistance drop of the armature plus the demagnetizing effect of armature reaction.

The quantities $(k_c' - L_c')$, $E_d M_{cf} P$, and $M_{cf} M_{(a+c)f}$ have been found to be negligible in this particular case. However, if necessary, they could be determined from relatively simple measurements on the machine. Neglecting these terms equation 15 reduces to

$$i_q = \frac{E_d}{(r_L + r_s - M_{(a+c)f})T_oP + r_L + r_s} \tag{16}$$

where $r_s = r_q + x_d''$, the synchronous resistance of the machine.

Substitution of equation 16 in equation 14 gives

$$I_d = \frac{E_d(r_L + r_s)}{(r_L + r_s - M_{(a+c)f})T_oP + r_L + r_s} \tag{17}$$

If E_d is a step function of time, then equations 16 and 17 have the solution[8]

$$i_q = \frac{E}{r_L + r_s}(1 - e^{-t/T}) \tag{18}$$

$$I_d = E_d(1 - e^{-t/T}) \tag{19}$$

where

$$T = \frac{(r_L + r_s - M_{(a+c)f})T_o}{r_L + r_s}$$

Hence, both armature and field current change exponentially to the new values when the field voltage is suddenly changed on a separately excited d-c generator.

The coefficients of equation 18 must be expressed in terms of per unit values of the armature circuit, whereas the coefficients of equation 19 are expressed in terms of per unit values of the field circuit. The value of T can be expressed in terms of per unit values of either the armature or field. If L_f is in henrys and R_d is in ohms, then T_o and t are in seconds.

To determine the correctness of the theoretical analysis given above, the constants of the machine are used in equations 18 and 19 to predict the transient currents of the generator operating under the conditions as previously stated. The equations for i_q and I_d, as determined in Appendix III, are respectively

$$i_q = 0.862(1 - e^{-t/0.38}) \text{ units}$$

$$_d = 0.862(1 - e^{-t/0.38}) \text{ units}$$

From the oscillograms shown in Figure 10, the armature current is found to rise exponentially from 16.5 to 25 amperes, the time constant, T, being 0.367 second. The shunt-field current rises in the same manner and has exactly the same time

Figure 6. Combined mutual inductance of the armature and commutating field with respect to the shunt field, as a function of the direct component of field current

constant. This agreement is much better than one has a right to expect, but indicates very well the accuracy of the assumptions and shows that the method of measurement is satisfactory.

Measurement of Machine Constants

Shunt-Field Inductance

The inductance of the shunt field must be determined accurately. Because of the large eddy current losses in the magnetic circuit, it is necessary to use a Hayes bridge when measuring the inductance of the shunt field. The inductance is measured as a function of frequency down to about 5 cycles per second. The data then are plotted on log-log paper and the curve is extrapolated to the very low frequencies. The d-c inductance also can be determined from the open-circuit time constant of the machine. The data for the inductance of the shunt field as a function of frequency and direct component of current are shown in Figures 2 and 3. The curves indicate that the operating conditions must be known if satisfactory values of inductances are to be used in the equations.

Mutual Inductance, $M_{(a+c)f}$

The mutual inductance, $M_{(a+c)f}$ is the most difficult of the coefficients to evaluate. To the author's knowledge, this quantity has never been measured before. This inductance is a "combined mutual" of the armature and commutating field with respect to the shunt field. Since for zero brush shift the armature reaction is in space quadrature with the shunt field, any change in the shunt-field flux linkages must be caused by the saturation of the pole tips. That is, as the main field flux is shifted toward one pole tip, due to saturation the decrease in flux on one side of the pole is greater than the increase on the other side. The mutual coupling is

Figure 8. Combined mutual inductance of the armature and commutating field with respect to the shunt field, as determined from the oscillograms of the transients

therefore a peculiar type of coupling and not a true mutual inductance in the ordinary sense of the word. However, the change in the shunt-field flux linkages is proportional to the armature current; therefore its effect upon the field circuit can be represented by an equivalent mutual inductance.

It was possible to measure this mutual inductance $M_{(a+c)f}$ by means of the bridge circuit shown in Figure 4. Fundamentally the circuit is the Hartshorn Method[11] of measuring impure mutual inductances. By an impure mutual inductance is meant one in which the voltage induced in the secondary is not in exact quadrature with the primary current. The adaptation of the Hartshorn Method to this problem is believed to be original. The data for the mutual inductance, $M_{(a+c)f}$ are shown in Figures 5 through 8. Because of excessive oscillations of the armature, it was not possible to obtain readings below 30 cycles per second by use of the bridge circuit. It also is impossible to extrapolate accurately the curve to zero even after plotting the data on semilog paper. Therefore, a second method was used to obtain the mutual inductance at zero frequency.

Solution of equation 14 gives

$$I_d = \frac{E_d + M_{(a+c)f} T_e P i_f}{1 + T_e P}$$

If the field voltage is held constant then

$$I_d = E_d + \frac{M_{(a+c)f} T_e P i_f}{1 + T_e P} \tag{20}$$

Furthermore, if the armature current is a step function of time, then equation 20 has the solution

$$I_d = E_d + M_{(a+c)f} i_f e^{-t/T_0} \tag{21}$$

From the oscillograms which were taken when a load was suddenly applied to the generator operating at constant speed, Figure 9, it is seen that the armature current does approach a step function of time. Only a small error will be introduced when it is considered as such. If $t=0$ in equation 21, then

Figure 9. Oscillograms of transients for sudden application of resistance load to separately excited generator, armature speed maintained

	I_f	I_a	V_f	V_a
	Initial Conditions			
(a)	0.37	0	109.0	258
(b)	0.44	0	124.0	280
	Final Steady-State Conditions			
(a)	0.37	15.3	109.0	230
(b)	0.44	30.0	124.0	230

$$M_{(a+c)f} = \frac{I_d - E_d}{i_f} \tag{22}$$

From equation 22 and the data taken from the oscillograms of the suddenly applied loads of 5, 7, 15, 20, and 30 amperes, the curve shown in Figure 8 was obtained. The importance of knowing the operating conditions to select the constants is again emphasized.

Conclusions

The general solution to the problem of transient current of a shunt-wound d-c dynamo having commutating poles and zero brush shift has been obtained. The necessary constants of the machine, including the mutual inductance between the armature and shunt field, have been successfully measured. When these measured constants are used in the equations to determine the transient currents, the results obtained are in close agreement with experimental data. The time constant of the machine tested was calculated to be 0.38 second, as compared to a measured time constant of 0.367 second.

The analysis is quite general in that it can be extended to include the transient analysis of almost any type of d-c dynamo. It is believed that the assumptions made in this analysis also will hold in most d-c dynamo transient problems without introducing excessive error.

As stated in the section on Assumptions, any shift in brush axis due to change in load is neglected. This means that any sparking at the brushes produced by rapid change in armature current is neglected. Furthermore, it has been assumed that the armature magnetomotive force and flux are in time phase, and the effect of eddy currents and hysteresis in the poles and yoke can be neglected. For machines with laminated poles these assumptions are reasonable.

The analysis given through equation 15 includes the effect of armature leakage inductance and is quite general. It is seen that equation 15 is of the second order in P and therefore a sine or hyperbolic sine term is expected in the solution. In going to equation 18 the coefficient of P^2 was neglected. This was a reasonable assumption to make for the machine under consideration because of the magnitude of the coefficient of P^2. Also, the fact that the oscillograms of the transients show no presence of a sine or hyperbolic sine term verifies the assumption. The fact that these additional transient terms are sometimes observed in practice simply indicates that for that particular machine the P^2 term is not negligible.

Although this first analysis has assumed constant armature speed, the analysis can be extended to problems in which constant armature speed is not maintained.

Appendix I. Nomenclature

φ_d = per unit flux linkages in the direct axis of armature
φ_q = per unit flux linkages in the quadrature axis of armature
γ_d = per unit direct-axis field flux linkages
γ_q = per unit quadrature-axis field flux linkages
i_d = per unit direct-axis armature current
i_q = per unit quadrature-axis armature current
e_d = per unit direct-axis armature voltage
e_q = per unit quadrature-axis armature voltage
r_d = per unit direct-axis armature resistance
r_q = per unit quadrature-axis armature resistance
I_d = per unit direct-axis field current
I_q = per unit quadrature-axis field current
E_d = per unit direct-axis field voltage
R_d = per unit direct-axis field resistance
x_1 = per unit leakage inductance of armature
x_d' = per unit fictitious inductance to account for armature reaction in the direct axis
x_q' = per unit fictitious inductance to account for armature reaction in the quadrature axis
x_d'' = per unit fictitious inductance of armature to account for saturation effect of i_q on the direct-axis field pole tips
$x_d = x_1 - x_d'$
$x_q = x_1 - x_q'$
L_q = per unit inductance of quadrature-axis field (commutating field)
L_f = per unit inductance of direct-axis field (shunt field)
$L_a' = L_q - M_{ac}$
M_{af} = per unit mutual inductance between armature and direct-axis field
M_{ac} = per unit mutual inductance between armature and quadrature-axis field
M_{af}' = per unit mutual coupling between quadrature-axis armature current and direct-axis field. This quantity accounts for the decrease in direct-axis flux as a result of the saturation of the direct-axis pole tips.
M_{cf} = per unit mutual inductance between direct- and quadrature-axis fields
$M_{(a+c)f}$ = per unit mutual inductance of armature and commutating field with respect to the shunt field = $M_{af}' - M_{cf}$
k_f = proportionality factor between direct-axis field current and the direct-axis flux linkages it produces with the armature at no load
k_c = proportionality factor between quadrature-axis field current and the quadrature-axis armature flux linkages it would produce if there were no armature current
$k_c' = k_q - X_q$ = proportionality factor between commutating field current and the quadrature-axis armature flux linkages it produces when $i_q = I_q$
T_o = open-circuit time constant of direct-axis field = L_f/R_d
P = operator, $\frac{d}{dt}$
unit e_d and e_q = rated terminal voltage at no load
unit φ_d and φ_q = flux linkages necessary to produce rated voltage at no load
unit i_d and i_q = rated armature current
unit I_d = field current necessary to produce unit φ_d at no load
unit γ_d = field flux linkages produced by unit I_d
unit P_o = rated armature speed
unit time = one second

Appendix II. Derivation of Armature- and Field-Voltage Equations

Field Voltage

If unit field voltage, E_d, is defined as that voltage necessary to produce unit I_d under steady-state conditions, then

$$E_d = CP\gamma_d + I_d$$

where C is a constant of proportionality between the voltage and flux linkages. Since unit E_d and γ_d were chosen independently of each other, C cannot be unity and therefore must be determined. Consider the condition when the field is shorted and the armature open-circuited. Under this condition $\gamma_d = I_d$, and

$$CP\gamma_d + I_d = 0$$

Also in conventional terms $PL_fI_d + I_dR_d = 0$

or

$$(T_oP+1)I_d = 0$$

Therefore

$$C = T_o \text{ and } E_d = T_oP\gamma_d + I_d \tag{23}$$

Armature Voltage

It is possible to express all flux linkages in equation 11 in terms of E_d and i_q. From equation 23 and equation 9

$$I_d = E_d - (I_d - M_{(a+c)f}i_q)T_oP \tag{24}$$

A substitution of equation 24 in equation 7 gives

$$\varphi_d = \frac{E_d}{1+T_oP} - \frac{[(M_{(a+c)f} - x_d'')T_oP - x_d'']i_q}{1+T_oP} \tag{25}$$

To determine γ_q as a function of E_d and i_d, substitute equation 24 in equation 10 to obtain

$$\gamma_q = L_a'i_q + \frac{M_{cf}(E_d + M_{(a+c)f}T_oPi_q)}{1+T_oP} \tag{26}$$

Upon substituting equations 8, 25, and 26 in equation 11 the expression for e_q in terms of E_d and i_q is obtained

$$e_q = Pk_c'i_q - P\left[L_a'i_q + \frac{M_{cf}(E_d + M_{(a+c)f}T_oPi_q)}{1+T_oP}\right] - r_qi_q + \frac{E_d + [(M_{(a+c)f} - x_d'')T_oP - x_d'']i_q}{1+T_oP} \tag{13}$$

Figure 11. No-load saturation curve of d-c machine used in checking analysis

Appendix III. Prediction of Transient Currents

The machine used for all the following experimental work was a $7^1/_2$-horsepower 230-volt 1,200-rpm shunt-wound dynamo. The machine was equipped with commutating poles and had zero brush shift. The frame was solid cast steel. The poles, pole shoes, and armature were about 50-mil laminated steel. Per unit values of the armature and field circuit are as follows:

PER UNIT VALUES OF FIELD CIRCUIT

$E_d = 90$ volts
$I_d = 0.314$ ampere
$R_d = 287$ ohms
$L_f/t = 287$ ohms
$t = 1$ second
$L_f = 287$ henrys

PER UNIT VALUES OF ARMATURE CIRCUIT

$e_q = 230$ volts
$i_q = 30$ amperes
$r_q = 7.67$ ohms
$L_a/t = 7.67$ ohms
$t = 1$ second
$L_a = 7.67$ henrys

Suppose the generator is operating under the following initial conditions: $E_d = I_d = 0.67$ unit, $i_q = 0.55$ unit, $e_q = 0.67$ unit. A step voltage of 0.67 unit then is applied to the field. The increase in armature current, i_q, is given by equation 18. From the initial conditions $r_L = 0.67/0.55 = 1.22$ units. From Figure 11, considering the load line to be a straight line over the range of operation from about 16 to 30 amperes, $rs = 1.67$ ohms $= 0.218$ unit. The analysis is based upon the assumption that the magnetization curve of the field is a straight line. From Figure 11 it is seen that this assumption may not be valid. Therefore, it is necessary to take the saturation effects of the field into consideration. This can best be done by drawing a straight line through the no-load point as shown in Figure 11. An equivalent value for E_d is then found by projecting horizontally from the no-load saturation curve to the straight line. The initial value of E_d, therefore, has an equivalent value, $E_d' = 0.75$ unit. After taking saturation into consideration, a step voltage of 0.67 unit is equivalent to 0.45 unit. Because of the wide variation in $M_{(a+c)f}$, it is necessary to use an average value between the operating points.

From equation 18 the increase in armature current is

$$i_q = \frac{0.450}{1.44} = 0.312 \text{ unit}$$

giving a final steady-state value of armature current

$$i_q = 0.55 + 0.312 = 0.862 \text{ unit}$$

For a shunt field current of about 0.32 ampere and an armature current between 16 and 25 amperes, the average value of $M_{(a+c)f} = 1.0$ henry or 0.130 unit as determined from Figure 8. The time constant is given by

$$T = \frac{(r_L + r_s - M(a^+c)f)}{r_L + r_s} \qquad T_s = 0.91 T_o$$

From Figure 2, $L_f = 122$ henrys and $R_d = 287$ ohms, from which $T_o = 0.42$ second, and $T = 0.33$ second.

The equations for the armature current and field current then become

$$i_q = 0.862(1 - \epsilon^{-t/0.33}) \text{ unit}$$

$$I_d = 0.862(1 - \epsilon^{-t/0.33}) \text{ unit}$$

Discussion

E. L. Brancato and **J. Cybulski** (Naval Research Laboratory, Washington, D. C.): The author has made a good start by describing the flux linkages in d-c machinery not as a whole but in two parts; one for those composing the armature flux linkages and the other for the fields. By similarly extending the derivations for synchronous machines of R. H. Parks[1] the author also has subdivided flux linkages in each group into those in the direct and quadrature axes.

Up to this point the author has been quite general and explicit. The assumption neglecting saturation of commutating pole tips is allowable if the load transients do not overly exceed rated load on the applicable machines.

However, the paper is not clear on certain points and the following comments are made in the hope that they can be clarified:

1. Is it correct to gather that the term $M_{af}\, i_d$ in equation 3 was neglected and not as was stated $M_{af}\, i_q$?

2. It seems that equation 6 is not complete if the term Pr_d is omitted.

3. Equation 9 is to follow from equation 3 when $M(a+c)f$ is defined equal to $M_{af} + M_{cf}$. How is such a substitution to occur if equation 3 does not now contain the term $M_{af}\, i_q$? An explanation is desirable for the assimilation of the term $Maf'\, i_q$ in equation 9.

4. How have the eddy current and hysteresis losses been taken into account in the evaluation of the constants of the machine?

The equations which have been developed, 18 and 19, are not very general in the true sense of the word for the following reasons: In the development of equation 15, the author has neglected or omitted several terms which were termed negligible. Subsequently he then neglected two other terms which form the coefficient of the operator of the second order and in effect reduces the denominator from a quadratic to a linear term to form equation 16. For the solution of armature current as a function of time from equation 16, the particular excitation function employed consisted of an incremental increase in the field voltage, a step function of time in the field. A complete solution of the more general equation, 15, results in a time function composed of a constant plus two exponentials with different time constants. Depending on circuit parameters and initial conditions the armature and field currents may then rise to a peak and then decay to a steady-state value or rise essentially in some exponential form to a steady-state value. For the type of excitation function employed, a step function voltage in the field, it is not surprising that there is a similarity between the rise of armature and shunt field current during test. The armature time constant is overshadowed in this case by the field time constant.

The author's equations, 18 and 19, for i_q and I_d respectively, illustrate a current rise from zero values at time equal to zero. From the test results which were presented it appears that these currents can be more correctly expressed by a constant term representing the initial conditions plus the terms defining the transient as a function of time. Employing the author's result the equations would have the following form

$$i_q = 0.55 + 0.312\left(1 - \epsilon^{-\frac{t}{0.33}}\right) \text{ units}$$

$$I_d = 0.55 + 0.312\left(1 - \epsilon^{-\frac{t}{0.33}}\right) \text{ units}$$

The author is commended for the original manner of measuring the term $M(a+c)f$. However, it should be noted that d-c tests were resorted to for calculating $M(a+c)f$ after the bridge circuit method was found to be unsuccessful. In those tests armature currents of approximately equal to the expected armature transients must be used. This restricts the application to low level transients. If it is expected that this approach may be extended to calculations of short-circuit currents it becomes necessary that the various quantities be calculated from machine constants. It is felt that such an extension would require modification of assumptions two and three, and a consideration of reactance voltage.[2]

G. H. Fett (University of Illinois, Urbana, Ill.): Mr. Koenig has indicated a method of predicting the transient response of a d-c dynamo by the use of parameters which can be measured. The test which he made on the generator shows that the method is accurate when the parameters can be evaluated carefully. There is at least an equal interest in the transient speed and torque characteristics of the d-c motor which also should be investigated.

Suppose that a d-c motor is controlled by varying the voltage across the armature with the field supplied from a constant voltage source. The equations which apply in this case are

$$(Jp + f)p\delta = M \tag{1}$$

$$M = K(-i_q x_d - i_d x_q) \tag{2}$$

$$e_q = (I_d - x''_d i_q)p\delta + pK'_c i_q - pL_c' i_q - M_{cf} p I_d - i_q r_q \tag{3}$$

$$I_d = \frac{E_d + T_o p M_{(a+c)f} i_q}{1 + T_o p} \tag{4}$$

where equations 3 and 4 can be derived from the author's equations 11 and 23 together with equations 7 to 10, and the symbols are those of the author with the addition of

J = moment of inertia of motor and load
f = viscous friction parameter
M = torque of load (used to avoid confusion with other symbols used by the author) and
K = a constant relating torque and motor current and flux

Let the second term in equation 2 be neglected and let E_d of the field be assumed constant. Then an expression relating i_q and the mechanical constants can be written by combining equations 1 and 2. Thus

$$i_q = -(Jp + f)p\delta / Kx_d \tag{5}$$

and from equation 9 of the paper

$$i_q = -(Jp + f)p\delta / K(I_d - M_{(a+c)f} i_q) \tag{6}$$

Equation 6 shows that the differential equation of speed as a function of i_q is nonlinear.

The nonlinearity results from the inclusion of the coupling term $M(a+c)f$ between armature and shunt field because of saturation of the main field pole tips. The analogy

is the steady-state analysis of a series motor, wherein the current-speed characteristics are nonlinear. If this coupling can be neglected, and Koenig's analysis shows that it cannot, then $M_{(a+c)f}$ and also x_d'' vanish. Use of this simplification gives

$$i_q = -(Jp+f)p\delta/K\ I_d \tag{7}$$

and

$$I_d = \frac{E_d}{1+T_d p} = E_d \tag{8}$$

so that

$$i_q = -(Jp+f)p\delta/K\ E_d \tag{9}$$

Now from equation 3

$$i_q = (e_q - E_d p\delta)/(pK_c' - pL_a' - r_q) \tag{10}$$

Hence

$$(Jp+f)p\delta/K\ E_d = (e_q - E_d p\delta)/(-pK_c' + pL_a' + r_q) \tag{11}$$

and

$$p\delta = e_q K E_d / [(Jp+f)(r_q + pL_a' - pK_c') + E_d^2 K] \tag{12}$$

The latter equation is the usual relationship which is given between speed and parameters of the motor system when the demagnetizing effect of armature reaction is neglected.

The method of attack which results in equation 12 of the discussion is not valid yet it is equation 12 which is commonly used to represent the d-c motor in the type of control described. It is to be hoped that the method developed by Mr. Koenig will be extended to the study of the solution resulting when equation 6 of the discussion is used for the armature current.

Attention should be drawn to the unusual method developed by Mr. Koenig to measure the mutual coupling between armature and field. To the discusser's knowledge this is the first time that the coupling is considered as an inductance and measured and handled as a simple circuit element. It also is important to note that this coupling is not a constant and that a value must be used consonant with circuit conditions. This is indicated in the author's Figures 5 to 8. It is seen that, depending upon the armature current, this mutual inductance varied from 0.4 to 1.2 henrys. Had an incorrect value of $M_{(a+c)f}$ been chosen, such as 0.4 henry, the value of the time constant T would have been approximately $0.964T_0$. Had $M_{(a+c)f}$ been neglected entirely, a 9 per cent error in time constant of the armature circuit would have resulted.

H. E. Koenig: With reference to Messrs. Brancato and Cybulski's question concerning the M_{af} term in equation 3, and $M_{(a+c)f}$ in equation 9, in the preprint of the paper an error was made in the definition of $M_{(a+c)f}$. In the final printing it is correctly defined as: $M_{(a+c)f} = M_{af}' - M_{cf}$. With this definition of $M_{(a+c)f}$, equation 9 follows from equation 3.

In connection with the question concerning the omission of the $P\gamma_d$ term in equation 6, the nomenclature in Appendix I reveals that γ_d is the per unit direct axis field flux linkages. Hence $P\gamma_d$ would represent the voltage induced in the direct axis or shunt field under transient conditions. The shunt or direct-axis field is certainly not connected in series with the direct axis armature winding. Therefore, the $P\gamma_d$ term should not be included in the expression for e_d in equation 6.

In equation 5, $P\gamma_q$ appears because the commutating field is normally connected in series with the armature and any voltage induced in this field must be included in the expression for the quadrature armature voltage e_q.

To answer the question as to how the eddy current and hysteresis losses are taken into consideration in the evaluation of the constants of the machine, the following will be helpful. Due to the eddy-current and hysteresis losses in a magnetic circuit, the flux cannot be in time phase with the magnetizing current. Since the voltage induced in any winding about the core is proportional to the time rate of change of flux, the voltage cannot be in time quadrature with the magnetizing current. Therefore the effect of eddy currents and hysteresis losses is to decrease the quadrature component and increase the in-phase component of magnetizing current. If a Hayes inductance bridge is used to measure the inductance, both components of current must be balanced before the bridge is completely balanced. Thus the effect of the eddy-current and hysteresis losses is to increase the apparent resistance and decrease the apparent inductance.

Likewise in measuring the mutual coupling, $M_{(a+c)f}$, the eddy-current and hysteresis losses appear in the form of an equivalent resistance and is often referred to as the impurity. From Figure 5, it is seen that the impurity decreases very rapidly with frequency so that at one or two cycles per second the effect of eddy-current and hysteresis losses on the mutual inductance is negligible.

A question has arisen as to the generality of equations developed. The author considers the equations up to and including equations 13 and 14 quite general. From that point on beginning with the section on Prediction of Transient, a special problem of a separately excited d-c dynamo having zero brush shift and equipped with commutating poles was considered to verify the analysis. Equations 13 and 14 then were simplified as permitted by the special problem under consideration.

The author wishes to thank Messrs. Brancato and Cybulski for pointing out the correction in equations 18 and 19. The equations as they stand give the increase in armature and field current respectively under transient conditions. The complete expression for the armature and field current is then the sum of a constant term and the transient term as they have indicated.

With reference to the discussion concerning the measurement of $M_{(a+c)f}$, it must be kept in mind that it is necessary to measure $M_{(a+c)f}$ at or near expected values of armature and field current only because of the saturation of the shunt field pole tips. Since the mutual coupling, $M_{(a+c)f}$, is due chiefly to saturation of the pole tips, there seems to be no other way of obtaining a satisfactory value. However, this does not limit the application of this analysis to low level transients. The d-c value of $M_{(a+c)f}$ can be determined for value of armature current near short-circuit values in the same way it was determined for the values of armature current in Figure 8. Thus, it seems possible to extend the armature current scale shown in Figure 8 to about short-circuit value.

When the constants of the machine are actually measured in this manner and used in the equations developed, some of the effects of hysteresis and eddy-currents are taken into consideration.

Reactance voltage does appear in the equations which have been developed since all flux linkages have been considered.

Maximum Short-Circuit Current of D-C Motors and Generators

AN AIEE COMMITTEE REPORT

THE transient characteristics of d-c generators and motors are matters of considerable interest to those who must know how these machines perform in other than steady-state conditions.

The response of the machine within normal loading is important to the engineer responsible for its utilization. What the time-current characteristics will be under short circuit conditions determines the degree of protection needed and the structure of the machine connections.

The D-C Machinery Subcommittee of the AIEE Rotating Machine Committee have individually and collectively devoted their time and thought to the theories which permit the calculation of transient characteristics.

Paper 50-23, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, January 30-February 3, 1950. Manuscript submitted November 1, 1949; made available for printing November 29, 1949.

This report was prepared by A. G. Darling of the AIEE Subcommittee on D-C Machinery of the AIEE Committee on Rotating Machinery.

Acknowledgment is made of the assistance given by R. G. Rhudy of the General Electric Company, Schenectady, N. Y., in the preparation of this material, and also to the various manufacturers of machine characteristics furnished by Allis-Chalmers Manufacturing Company, General Electric Company, and Westinghouse Electric Corporation.

Individual investigators have advanced methods[1,2,3] for the determination of these characteristics. Where test data have been available, they have been compared with calculated results and modifications made accordingly.

As a first step in assigning parameters to the basic characteristics

r_d' per unit equivalent resistance
l_a' per unit inductance
l_{as}' per unit saturated inductance

several manufacturers have applied the selected theories[2,3] to typical machine constants and have obtained values of r_d' as a first step in the ultimate program.

As progress is made in the determination of inductances, it is expected that similar analysis and confirmation by test will be forthcoming.

While a number of references were tried by which to relate the value of r_d' to the particular machine, those that appeared to have the most usable and sound basis are the product of rated output in kilowatts or horsepower, depending on the machine being a generator or a motor, by its rated speed in, N, revolutions per minute.

Refinement of design, such as types of field windings, appear to have an effect on the r_d'. The principal differentiation, however, seems to be between machines with and without pole face windings.

In order not to confuse the investigator too greatly, it has been felt that for the present, at least, no sharper classifications should be attempted in respect to field windings.

Considerable differences appear in the various voltage, temperature rise, and utilization classes of machines. By utilization is meant such classes as general purpose, National Electrical Manufacturers Association (NEMA) ratings and traction or mill motors.

Figures 1 to 9 inclusive, showing the relation between r_d' and the product of the output (kilowatts or horsepower) and rated speed N, were, accordingly, made to include as broad classifications of design as would preclude an unacceptably wide dissimilarity of r_d'.

In each instance a median line following the trend of the points was drawn. Beside this, guide lines, showing practically the outside limits of r_d', were added.

From these, it is expected that the investigator can be as optimistic or pessimistic as he wishes to be but still stay within the realm of reality. Obviously, if the case warrants it, specific data for specific machines should be obtained from the machine designer.

All values of r_d' assume base (minimum rated) speed and voltage and no load on the machine.

Characteristics of Some Magnetic-Fluid Clutch Servomechanisms

A. J. PARZIALE
ASSOCIATE AIEE

P. D. TILTON
ASSOCIATE AIEE

A MAGNETIC-FLUID clutch transmits torque through the shear resistance of a mixture of iron powder and fluid. This "magnetic fluid" fills the gap between the faces of the clutch, which also are magnetic poles, and it "freezes" or solidifies when the small particles of powder cling together in the presence of magnetic flux. Torque is controlled smoothly by changing the magnetic field strength to vary the consistency ot the mixture and therefore its mechanical resistance.

In 1948, Jacob Rabinow at the National Bureau of Standards first reported such a clutch.[1] Its advantages for use in servomechanisms are its small size, simplicity, fast action, freedom from wear, smoothness, and a large ratio of output power to control signal power.[1,7,8]

The experimental work described herein is part of a preliminary investigation of magnetic-fluid clutches conducted by the Servomechanisms Laboratory, Massachusetts Institute of Technology under the sponsorship of the United States Air Force, Air Material Command, Wright Field. It is not related to the development of any specific application or apparatus, but seeks only to indicate the basic nature of the clutches and to evaluate their characteristics as servomechanisms components.

Description of Clutches

Figure 1 is an experimental magnetic-fluid clutch designed by the authors from early information published by the National Bureau of Standards.[1] The disk-type design was chosen to provide a means for adjusting the clutch gap clearance and to avoid seals or slip rings. The shafts are vertical, the clutch chamber is an enclosed cavity in the rotor, and the coil to energize the magnetic circuit is contained in a concentric stator out of which the flux passes radially to and from the rotor through annular air gaps. The clutch gap is adjusted by the rotor spacing screws which determine the space between the two parts of the rotor; the centering nuts on the disk shaft are used to equalize the gaps between the disk and the rotor. This experimental clutch is considerably larger, more complex and less efficient than is necessary to develop the same amount of torque.

Figure 2 is a cross-section of a clutch made by the Raymond Engineering Laboratory, model *731*. Although designed for laboratory use and investigation, it illustrates the simplification which is possible in clutches for commercial use, when experimental flexibility is not the objective. This clutch was intended to produce rapid response and, therefore, is a disk type with low output shaft inertia Its coils are wound for high impedance and dissipate about ten watts. A small field time constant can still be achieved by use of appropriate electronic amplifier output stages.

Table I is a comparative summary of important design data for the two clutches. Except where noted, the experimental clutch was used with a 0.032-inch clearance gap. The Raymond clutch had a gap of 0.015 inch for all studies.

A single clutch can exert torque only in the direction of its drive motor. One convenient method of obtaining a reversible servomotor is the arrangement shown in Figure 3. The continuously-rotating prime mover drives two clutches in opposite directions so that the net torque on the output shaft is equal to the difference of the opposing torques of the two individual clutches. The double clutch unit can drive in either direction, depending on which clutch is energized. The clutch coils are the balanced load for the push-pull output stage of an electronic power amplifier. This push-pull arrangement of the coils and of the clutches improves the linearity of the torque-current characteristic, as shown in Figure 4. When the bias current in each coil is properly adjusted, the output torque of the 2-clutch servomotor is proportional in the steady-state, to the differential current in the field coil circuit, and the region of very low gain (small slope) near the origin is eliminated. Improved linearity is obtained by sacrificing considerable energy, because the quiescent coil current results in opposing clutch torques at zero signal (differential coil current) that are from three to five times as large as the residual drag.

Steady-State Clutch Characteristics

The static torque-current curves for single clutches are shown in Figure 5. These curves show complete hysteresis loops, and indicate that the maximum torque deviations attributable to hysteresis amount to about 150 inch-ounces or approximately 12 per cent of rated torque for the experimental model, and almost 200 inch-ounces or 16 per cent of rated torque in the case of the Raymond model *731*. The clutch torque as a function of the coil current depends upon the reluctance of the magnetic circuit. The total reluctance is composed of the reluctance of the iron-oil gap and the re-

luctance of the field core as determined by the material, length, and relative flux densities of the various core sections. If, as presently believed, the magnetic fluid has almost constant permeability,[1] a clutch with a large gap and a short iron core will tend to have flux density more nearly proportional to the magnetomotive force and over a wider range than if there is more iron and less gap. The shape of the magnetization curve for a magnetic-fluid clutch will be characterized by the magnetization curve for the iron core, but it is more linear when the gap contributes a larger portion of total reluctance. Although data of flux density versus magnetomotive force for the iron-oil mixture are difficult to obtain, the average per-

meability of thick mixtures (9/1 by weight) has been reported as ranging from four to eight times that of air.[1,9]

The shear resistance of the iron-oil mixture as a function of magnetic field strength is the fundamental property of importance in the design of controllable clutches. Clutch torque is the product of the average shear stress in the fluid and a geometric factor that is equal to the active area of the clutch face times its mean effective radius. The magnetic field strength is determined by the design and excitation of the iron core, as noted previously. Its variation to control the clutch is obtained usually by varying the core magnetomotive force due to the coil current, although mechanical motion to alter gap spacing or the position of a permanent magnet might be used. The basic relationship of the magnetic fluid is obtained easily from torque versus current curves if the geometric factor can be evaluated for the design and the magnetization curve, flux density versus current, of the clutch is known.

Figure 6 gives curves of shear stress versus flux density for several different clutch gaps. The data were taken in the experimental clutch model for which the flux densities at several values of coil current and different gap spacings had been measured by means of a ballistic galvanometer connected to a search coil which was placed around the periphery of the disk to link the flux. For these curves, the shear stress varies as a power of flux density. The exponent ranges from 1.3 for 0.060-inch gap to 2.0 for a 0.045-inch gap. The other exponents are: 1.5 for a 0.020-inch gap and 1.7 for a 0.032-inch gap. Almost any exponent from about 1.4 to 1.7 can be used to fit all curves with an accuracy of about ten per cent if the scale factor used to match experimental data is based on a point above 6,000 gauss. Within the range of flux densities covered by Figure 6, the shear stress, and hence clutch torque, were apparently still increasing as the flux density increased. The reasons for shear stress variation with different gaps and the same flux density are not clear, nor are the data sufficient to show the complete relationship between stress and gap spacing.

Figure 6. Static shear properties of magnetic fluid

Tests using different oils and synthetic fluids show that the steady-state magnitude of the shear stress is not affected by the fluid characteristics. The Raymond clutch used light machine oil and the experimental clutch employed a light oil compounded for upper-cylinder lubrication of automobile engines. Carbonyl SF iron powder has a smaller, more uniform particle size (between 1 and 4 microns) and gave slightly less shear resistance than the Carbonyl E, which has a wider range of particle size (3 to 12 microns). The data of Figure 6 apply only to a 9-to-1 mixture (iron-to-oil, by weight) which was selected as the thickest likely to be feasible and therefore is representative of the maximum effect of iron concentration. Thinner mixtures produce somewhat less shear resistance for the same current in any given clutch. The choice of gap size and iron/oil ratio is usually determined in design by consideration of allowable drag, torque/current sensitivity and convenience in handling and filling. The two clutch models of these tests do not provide a sufficient basis for completely ascertaining the effect of gap spacing, mixture ratio, slip speed, or fluid properties upon the speed of response. Correlation with the results of tests on several other types of design will be required before general design data can be established.

An expression to describe the state of the magnetic fluid has not been formulated, but the curves of Figure 6 suggest a relationship akin to that of the force of attraction between extended magnetic poles separated by a small gap, namely

$$F = c\frac{B^2A}{\mu} \tag{1}$$

where

F = force
B = flux density in the gap
A = area of the gap
μ = relative permeability of the gap medium
c = a constant of proportionality

Such an expression may apply to the creation of transverse shear stresses by the action of the normal pressure force, F, on the solid iron particles. Resistance to shearing is developed from the effective coefficient of friction, either between layers of particles or at the clutch faces, and also may include components of the magnetic forces which bind the iron particles together. The shearing stress exerted by the partially "frozen" or solidified iron-oil mixture is related to the formation of linear chains, each consisting of several individual spherical particles of the iron powder, which cling together and align themselves with the direction of the magnetic field. This formation has been observed microscopically with very "wet" mixtures in fairly weak fields and without relative motion between pole faces, but these observations alone cannot produce a sufficiently definite understanding of the phenomenon.

The observed variation of shear stress as the flux density raised to some power between the first and second indicates that the square-law expression suggested before is not adequate even if allowances are made for extremes in the variability of the friction coefficient. At the same time, the results cannot be explained on the basis of a strictly linear function. Apparently some of the chains pull tight together and saturate, each one adding a fixed incremental force to the shear resistance, while other chains are not completely saturated and contribute force components that vary as the square of the flux density. Thus, the resultant function for the total resistance seems to vary with an exponent somewhere in between these extremes.

For single clutches, torque is virtually independent of speed except at large values of exciting current, as shown in Figure 7. The drag torque at zero current is caused by residual magnetism in the magnetic core and viscous shear resistance of the fluid mixture. It is normally of the order of three to five per cent of maximum clutch torque, but if necessary it may be held below one per cent by the use of large gaps and thin mixtures.[1] The exact magnitude of the drag is seldom important in servos employing the push-pull arrangement, since it has only a minor effect on the bias adjustment for linearity. The drag of one clutch is balanced by that of the other in the 2-clutch servomotor.

Dynamic Response

Shear Phenomenon of Magnetic Fluid

The dynamic relation of clutch torque to coil current is characterized by a first-order time lag. This is determined from tests of the response of both single clutches and the push-pull servomotor to sinusoidal and transient input disturbances. Instantaneous measure of the torque was obtained by restraining the clutch output shaft in a fixture containing a conventional strain gage bridge. Coil current was measured by the voltage across a resistor in series with the coil. In actual application, where the time constant which relates torque to voltage is relevant, the voltage-to-current time constant also must be considered. It has been stated in reference 2, page 328, that the actual field time constant for a small generator excited by a vacuum tube may be in error by as much as a factor of six if effects of eddy currents, shorted turns, and so forth are ignored.

Figure 8 shows the attenuation and phase response of stall torque as a function of coil current. This figure applies to two experimental clutches in push-pull, with a sinusoidal input signal of constant amplitude and variable frequency. The shape of the curve indicates that the transfer function of the double clutch actuator may be given as

$$\frac{T(s)}{I(s)} = \frac{K_c}{T_c s+1} \tag{2}$$

where $T(s)/I(s)$ is the Laplace notation[4] for the torque-to-current transfer function in terms of the complex variable, s, K_c is the steady-state torque-current sensitivity of the clutches and T_c is the time constant of response. From Figure 8 the break frequency of the curve's asymptotes at about two cycles per second indicates a clutch time constant, T_c, of 70 to 80 milliseconds for the experimental clutch model.

The time constant for the torque-to-current response of a magnetic-fluid clutch may possibly be due to several effects other than a lag in the magnetic fluid itself due to the finite time required for the particles to form into chains. The magnitude of this lag must be verified for there is considerable disagreement between the findings of different investigators. Additional lag between clutch gap flux and coil current may be caused by eddy currents in the solid iron core or by the transformer action of nonmagnetic, conducting rings used as spacers which link the flux. In a private communication, C. K. Stedman, Boeing Airplane Company, calculated the time constant introduced by the transformer action of the brass spacer ring in the experimental clutch to be about 80 milliseconds. Experimental determination of the relative importance of the magnetic lag effects will be required to establish the magnitude of lag in the mixture itself.

Transient response tests on single clutches disclose that the time constant for an increase of torque is considerably longer than that for a decrease. With the experimental clutch, the time constant for torque release was about 80 milliseconds and that of build-up about 120 milliseconds. The discrepancy between these values and that obtained from sinusoidal tests of the push-pull arrangement cannot be fully explained. The Raymond model *731* clutch also showed a difference between build-up and release time constants, with values of about 20 milliseconds for release and about 40 milliseconds for build-up, but no comparison was attempted with this type of clutch in the push-pull arrangement.

An explanation of the difference between the time constants for build-up and release of torque in response to step-functions of current lies in the difference in the creation and release of shear resistance in the magnetic fluid. The physical forces acting on the particles are those of: attraction due to the presence of a magnetic field, which forms chains to give minimum reluctance flux paths; a variety of forces tending to disrupt or disturb the chains, among which may be included centrifugal forces, frictional, or other forces of mechanical contact due to particle density and relative motion between the clutch, faces, and fluid forces due to film strength, surface tension, and viscosity. Torque is developed at a rate depending on the speed with which the particles form into chains, but the release time is governed by the magnitude and speed of action of the various disruptive forces. There is no reason to suppose that both actions will take place with equal rapidity. The build-up time of the magnetic flux is equal to the release time, so this factor is insignificant when considering the difference between build-up and release times of the torque.

Figure 8. Torque/current frequency response of experimental 2-clutch servomotor

Figure 10. Inverse transfer function loci used to determine damping coefficient of 2-clutch servomotor

The faster response of the Raymond clutch may be attributed to: a smaller magnetic core; the use of a smaller gap clearance; a somewhat thinner mixture; and the addition of a wetting agent. The small core of the model *731* reduces eddy current lags. The smaller gap and more fluid mixture cause a faster action because of better mixing and fluid film conditions for quick motion of the iron particles in forming chains. Further investigation will be required to verify the causes of the time lag and to discover how the design factors influence it.

Double-Clutch Servomotor

The shear torque of a single magnetic-fluid clutch is independent of speed of rotation of the output, except at high values of current, as shown in Figure 6. This torque-speed characteristic is similar to that of other servomotors such as 2-phase a-c torque motors, which, when idealized, have no damping (decrease in torque output with increase in speed). With pure inertia loads such devices produce accelerations proportional to the applied signal. The servomotor characteristic is then described as a double integration, since the instantaneous position of the inertia shaft θ_o, is nearly proportional to a double integration with respect to time of the input signal.

By using equation 2, and equating applied and load torques, the transfer function for the output position of a single clutch and inertia load, J, may be expressed as

$$\frac{\theta_o(s)}{I(s)} = \frac{K_c}{Js^2(T_c s+1)} \tag{3}$$

Since the magnetic-fluid clutch never has less than 180 degrees of phase shift (a torque source), its use in a closed-loop position system will result in an unstable system unless some form or compensation is used.

The clutch servomotor using two experimental clutches in push-pull exhibits a small amount of damping in its performance.

This damping was found insignificant in stabilizing the closed-loop system, but it leads to a revised transfer function for a double clutch actuator, which is contrasted with that for a single clutch.

$$\frac{\theta_o(s)}{I(s)} = \frac{K_c/f}{s(J/fs+1)(T_c s+1)} \tag{4}$$

where f is the effective coefficient of damping. For ease in making analytical comparisons, it is convenient to treat the damping as viscous, although its source lies in many effects, some of which are more coulomb than viscous. Equation 4 differs from equation 2 which is applicable in the case of the 2-clutch actuator only when the output shaft is restrained, that is, no damping because of no output motion.

System Performance

The effective damping which the push-pull clutch unit introduces into the system was not measured directly. The effective value for the coefficient of damping, f, in a servomechanism system was determined from a comparison of calculated and measured data for a closed-loop positional response to sinusoidal inputs.

The basic servomechanism system was comprised of a standard synchro data system, a-c amplifier, full-wave demodulator, push-pull d-c power amplifier, the tachometer feed-back channel, and the clutch actuator, as shown in the block diagram of Figure 9. In this system, the time constant for the demodulator, T_d, was less than one millisecond and that for the power amplifier and clutch coil circuit, T_a, was about four milliseconds. These two time constants were small enough in comparison with the others to be neglected. The linear equations describing the system are given in the Appendix. Table II gives numerical values for the different system constants used in the various tests to be described.

*Not calculated, use measured values.

**Indeterminate, since no value obtained for f.

The experimental data to evaluate damping were taken with the experimental clutch servomotor and direct tachometer feedback for stabilization. The gain constants and coil bias current were adjusted for linear, stable operation to provide valid comparison with curves based on linear theory and calculated from equations 14 and 15 of the Appendix. Response data were calculated for a system inertia of 98 ounce-inches-squared for the experimental clutch, a value for the clutch time constant, T_c, of 0.08 second, and measured gain settings as given in Table II. Several values of the damping, f, were tried in the calculations, of which 15 inch-ounces per radian per second matches the experimental data well, as shown in Figure 10. No evaluation of the damping in the Raymond clutch system was attempted.

One set of the curves of Figure 10 applies to the output/error transfer function of the system and includes tachometer feedback but without the high-pass filter shown in Figure 9. The other set of curves in Figure 10 has been modified to exclude the tachometer effect, and therefore represents the inverse transfer function for the direct-path elements, of which only the clutch actuator and the load contribute dynamic effects in the range of frequencies considered. The J/f time constant for the clutch and load is about 0.017 second and its effect upon the system response is negligible below 10 cycles per second. The damping value of 15 inch-ounces per radian per second is less than one-tenth the effective feed-back damping from the tachometer.

Adjustment of the gain factors of the experimental system with tachometer feedback for optimum servo performance gave a greatly improved closed-loop positional response, shown in Figure 11. The optimum conditions were taken to be those permitting the highest cut-off frequency, ω_r, and the largest amount of system gain with a peak amplitude ratio, M_p, of between one and two. The output/input response is only slightly attenuated at about 13 cycles per second where cut-off occurs with a slope of 18 decibels per octave that is characteristic of a third-order system. For the optimum system gain adjustment, the torque constant, K_T, is 4,000 inch-ounces per radian and the velocity constant, K_v, is 37 radians per second per radian. The former constant is an index of the system position stiffness. The latter is a figure of merit defined as the steady-state velocity per unit of displacement error, ϵ, required to follow that velocity. Both relations are derived in the Appendix.

The velocity constant, K_v, may be increased considerably by the addition of a conventional high-pass filter in the feed-back loop.[8] The effect of the high-pass filter is apparent from a comparison of the expressions defining the velocity constant with and without the filter, equations 17 and 19 in the Appendix. These indicate a factor of increase of about 20 for the clutch system with the numerical gain values for optimum response in Table II. Experimentally, the addition of the filter increased K_v by a factor of 23.4 for the experimental clutch and 17.1 for the Raymond 731 clutch.

The addition of the high-pass filter causes a higher system gain factor in the case of a steady-velocity input. Ordinarily, the voltage to the power amplifier,

Figure 11. Closed-loop position response of servomechanism system with experimental 2-clutch servomotor

Figure 12. Closed-loop position response of system using Raymond 731 clutches

E_a in Figure 9, is smaller than the error voltage (E_e) by the amount of the tachometer feed-back voltage. Reduction of the latter enables a smaller system displacement error, ϵ, to generate the same amount of torque required at the output. The high-pass filter is capacitor-coupled, and at low frequencies it greatly attenuates the steady d-c voltage from the tachometer at the constant velocity of the system. In the case of a steady-state velocity, then, the torque per unit error (gain) is greater with the filter, than without it, and K_v is increased. The filter still permits the stabilizing feed-back signal to be introduced into the loop under transient or oscillatory conditions when damping is important.

The frequency response is not affected greatly by inclusion of the filter, as shown in Figure 11, although there is some augmentation of the amplitude ratio at low frequencies. For both clutch systems the time constant of the filter, T_f, was about 120 milliseconds to give a fairly low break frequency of 1.33 cycles per second. Above this frequency, virtually all of the stabilizing influence of the tachometer feed-back signal is retained.

The closed-loop response of the system using Raymond *731* clutches is given in Figure 12. These response curves reflect the smaller time constant noted previously for this clutch. The velocity and stiffness constants are considerably larger because the lower system inertia of about 20 ounce inches-squared with this model permitted more direct gain and less tachometer feed-back gain for the same relative stability. The frequencies of the last amplitude peak before cut-off are about 32 cycles per second with the high-pass feed-back filter, and 37 cycles per second without filter. These are more than double the corresponding frequencies of 12 and 13 cycles per second for the experimental clutch, which has twice the time lag of the Raymond clutch and five times the inertia. The very stiff torque constant of 6,350 inch-ounces per radian (without filter) and the high velocity constant of 1,375 radians per second per radian (with filter) for the Raymond clutch system indicate the good potentialities of magnetic-fluid clutches in high-accuracy servomechanisms. The performance of the two magnetic-fluid clutch servomechanisms described here compares favorably with other tests reported previously.[7,8]

Conclusions

Normal servomechanism design practice and familiar compensation techniques are applicable to systems using magnetic-fluid clutch servomotors. Optimum clutch design depends upon the nature of the system in which it is to be used. The speed of response of any particular clutch depends upon the clutch's size and design. It can be determined best by construction and test, although rough estimates from similar clutches may be made. Continued investigation with clutches of different sizes and configurations will establish the influence of design variables upon dynamic performance.

Among the several service limitations which must be overcome by further development, the following have been noted in these tests:

Magnetic Fluid

The iron-oil mixture must be able to withstand operation at temperatures as high as several hundred degrees Fahrenheit for long periods of time. The fluid propreties must prevent packing or settling of the iron powder into a dense, hard-packed mass during periods of storage or inactivity. This condition may be alleviated by the use of a wetting agent and a "warm-up" period of operation to stir the mixture.

Seals

Seals or labyrinth design to prevent loss of fluid must have long-life and be able to withstand the high temperatures encountered and abrasion from the iron powder. Face-type seals with hard graphite elements will probably surpass the conventional shaft or bearing seals under the severe service conditions usually imposed by magnetic-fluid clutches.

Heat Dissipation

Magnetic-fluid clutches, like some other servomotors, must be designed to dissipate the heat generated by working against load torques while stalled. The allowable temperature rise will be limited by the high-temperature properties of the coil insulation, the fluid, the seals, and other critical materials in the clutch.

Coil

Special protection of the winding insulation against high transient voltages, high temperature and abrasion is essential for reliable operation. Clutch sensitivity and coil time constant are affected by the coil design, which must be based upon the characteristics of the electronic power amplifier. For most applications, the coil heating will be negligible when compared to the mechanical heating due to slip.

The magnetic-fluid clutch is adaptable to many control applications besides its use as a servomotor. Other uses, as brakes, dynamometers, spring or damping simulators, and general purpose torque-loading devices for electromechanical mock-ups,[6] suggest themselves.

Appendix

The following equations which describe a servomechanism employing magnetic-fluid clutches are derived in terms of Laplace notation. A complete treatment of this method is given in references 2, 3, and 4.

General Transfer Function for the Complete System Employing Two Clutches in Push-Pull

The system transfer function is developed from the transfer functions of the individual components of the block diagram. An experimental determination of the dynamic response of a magnetic-fluid clutch indicates the transfer function given in equation 2

$$\frac{T(s)}{I(s)} = \frac{K_c}{T_c s+1} \tag{2}$$

where $T(s)$ is the Laplace transform of the clutch output torque, $I(s)$ is the transform of coil current, s is the Laplace complex variable, K_c is the steady-state torque-current sensitivity, and T_c is a characteristic time constant of the clutch response.

The load dynamics for the 2-clutch servomotor are taken into account by using equation 2 to equate the applied torque to the inertia and damping load torques, which gives

$$\frac{\theta_o(s)}{I(s)} = \frac{K_c/f}{s(T_c s+1)(J/f\, s+1)} \tag{4}$$

where J is the load inertia and f is the coefficient of the equivalent damping which is characteristic of the push-pull clutch arrangement, but is not noticeable in single clutches. The inductance-reactance time constant is considered negligible.

Incorporating the amplifier and demodulator gain factors, K_a and K_d respectively, in equation 4 gives the transfer function of the direct path, which omits tachometer and position feedback.

$$\frac{\theta_o(s)}{\epsilon(s)} = \frac{K'}{s(T_L s+1)(T_c s+1)} \tag{5}$$

where

$$K' = K_c K_a K_d K_s/f \tag{6}$$

$$T_L = J/f \tag{7}$$

The system transfer function, with position feed-back loop open, includes the tachometer feed-back loop around the power amplifier, clutch unit, and load. The tachometer loop includes a high-pass filter with a transfer function, $G_f(s)$ which is treated in more detail in the Appendix. For the system without feed-back filter, $G_f(s) = 1$. The equation for the open loop system can be expressed most conveniently in inverse form. The reciprocal of equation 5 is modified to incorporate the feed-back signal at the proper gain level.

$$\frac{1}{KG(s)} = \frac{\epsilon(s)}{\theta_o(s)} = \frac{s(T_L s+1)(T_c s+1)}{K'} + \frac{K_f}{K_a K_d} sG_f(s) \tag{8}$$

The closed loop response equation for the system described by the block diagram, Figure 9, may be found from the relation

$$\frac{\theta_o(s)}{\theta_i(s)}=\frac{KG(s)}{1+KG(s)}=\frac{1}{\dfrac{\epsilon(s)}{\theta_o(s)}+1} \tag{9}$$

$$\frac{\theta_o(s)}{\theta_i(s)}=\frac{1}{\dfrac{1}{K'}s(T_Ls+1)(T_es+1)+\dfrac{K_f}{K_sK_d}sG_f(s)+1} \tag{10}$$

Inverse Transfer Functions Used for Evaluating System Damping by Comparison with Experimental Result

The effective damping of the 2-clutch servomotor was evaluated by a comparison of experimental results with theoretical dynamic behavior of the system. This damping is associated with elements in the inner loop of the block diagram of Figure 9. For convenience, all of the damping is postulated as being associated with the load. This permits the concept of an idealized clutch and a single, lumped value for the coefficient, f, which is included in the load time constant, T_L, and the gain factor, K', in equations 6 and 7.

The experimental data were taken with the tachometer loop closed but without the filter, and the position loop open. This configuration is represented by equation 8 with $G_f(s)$ equal to unity. For response to a sinusoidally varying signal of constant amplitude and variable frequency the transform equation can be restated in terms of the real time frequency, ω. This transformation of variable in the Laplace method consists of replacing the complex variable s, by the complex frequency $j\omega$. Equation 8, letting $s \rightarrow j\omega$ and $G_f(s)=1$, then represents the system for the test conditions.

$$\frac{1}{KG(j\omega)}=\frac{(j\omega)[1+j\omega T_L][1+j\omega T_e]}{K_cK_aK_dK_s/f}+(j\omega)\frac{K_f}{K_sK_d} \tag{11}$$

The inverse transfer function vector, $1/KG(j\omega)$ may be calculated from equation 11 for any frequency, ω, if values for the individual gain constants, the clutch time constant, T_c, and the output inertia, J, are known from measurements. Several assumed values for f may be tried to calculate the locus of equation 11 which most nearly matches the experimentally determined locus. These two loci for the system with tachometer feedback are shown in Figure 10.

Figure 10 also shows calculated and experimental frequency response loci of the clutch and load without the tachometer feedback. The dynamic characteristics of the clutch and load are components of the greatest interest and these components comprise the direct path of the inner loop of the block diagram, Figure 9. The inverse transfer function for this path is

$$\frac{E_a(j\omega)}{\theta_o(j\omega)}=\frac{(j\omega)[1+j\omega T_L][1+j\omega T_e]}{K_cK_a/f} \tag{12}$$

Equation 12 is derived from equation 11 by a scale change to compensate for removal of the gain factor, K_sK_d, and a vector subtraction of the tachometer feedback term, $(j\omega)K_f$. Values for these changes can be evaluated readily from the experimental conditions. Calculation of the locus of equation 12 and revision of the experimental data for the same gain change and subtraction of tachometer feedback give the curves of Figure 10 for the clutch and load.

System Torque, or Stiffness Constant K_T

The stiffness constant, K_T, is the torque required in the steady state at the output for one radian of output angular displacement (error). It is the product of the sensitivities of all the feedforward components, that is, total direct gain contributing to torque.

$$K_T=K_sK_dK_aK_c\ \frac{\text{inch-ounce}}{\text{radians}} \tag{13}$$

Velocity Figure of Merit K_v, and Effect of High-Pass Filter in Tachometer Loop

A convenient criterion of the ability of positional servomechanisms to follow a steady velocity with minimum error is the velocity constant, K_v. This figure of merit is defined as the steady-state velocity per unit of displacement error. It is specified mathematically from the system transfer function, $KG(s)$.

$$K_v=\text{Lim}_{s\rightarrow 0}[sKG(s)]=\text{Lim}_{s\rightarrow 0}\left[\frac{s\theta_o(s)}{\epsilon(s)}\right] \tag{14}$$

From the inverse transfer function of equation 8

$$\frac{1}{K_v}=\left[\frac{(T_Ls+1)(T_es+1)}{K'}+\frac{K_f}{K_sK_d}\,G_f(s)\right]_{s\rightarrow 0} \tag{15}$$

where $G_f(s)$ denotes the transfer function of the high-pass filter.

$$K_v=\frac{1}{\dfrac{1}{K'}+\dfrac{K_f}{K_sK_d}\,[G_f(s)]_{s\rightarrow 0}}=\frac{K'}{1+\dfrac{K_fK'}{K_sK_d}\,[G_f(s)]_{s\rightarrow 0}} \tag{16}$$

Without the filter, $G_f(s)$ is equal to unity, and the velocity constant is

$$K_v=\frac{1}{\dfrac{1}{K'}+\dfrac{K_f}{K_sK_d}}=\frac{K_T}{f+\dfrac{K_fK_T}{K_sK_d}} \tag{17}$$

The effect of the filter function $G_f(s)$ or $G_f(j\omega)$ upon K_v is evident if it is considered in equation 16.

For a high-pass filter

$$G_f(j\omega)=\frac{j\omega T_f}{1+j\omega T_f} \tag{18}$$

T_f is the resistance-capacitance time constant of the filter circuit. The limit $s \rightarrow 0$ in equation 16 corresponds to $\omega \rightarrow 0$ in equation 18, for which $G_f(\omega) \rightarrow 0$.

The value of K_v in the limit of equation 16 is

$$K_v=K'=\frac{K_T}{f} \tag{19}$$

The increase in K_v at low frequencies (where $\omega << 1/T_f$) may be noted by comparing equations 17 and 19. At high frequencies, where $\omega >> 1/T_f$, the function $G_f(j\omega) \rightarrow 1$, and the full effect of the tachometer stabilizing signal is retained. The filter does not affect the stiffness, K_T, nor does it greatly alter the system transfer function.

Application and Handling of Very Large Power Transformers on the System of the Bonneville Power Administration

RICHARD F. STEVENS
MEMBER AIEE

IN April 1938, the first power from a Federal dam on the Columbia River was marketed when the street lights of the little town of Cascade Locks, Oreg., were lighted with power brought over a 13-kv line from Bonneville. At the same time, design was starting on the 230-kv grid which was to become the power backbone of the Pacific Northwest. The first large power bank was energized at 230 kv in December 1940.

Only nine years have elapsed since then, yet the Bonneville Power Administration (BPA) now has 18 230-kv banks on its system with a total maximum continuous capacity of over 2,000,000 kva. In the nine years to follow, as other Federal power plants are put in service, this is expected to increase to 46 banks with a capacity of over 7,500,000 kva.

BPA has thus become one of the most important users of large, high-voltage transformers, and as such, its transformer practices may be of interest.

These practices have undergone an interesting evolution. Changes have been in the direction of decreasing costs, wherever operating experience and engineering studies have shown this possible without loss of reliability. In this case, there existed, beyond the normal responsibility for keeping down costs, a strong desire to offset the rising trend of labor and material prices by savings which would make possible a continuance of the low wholesale rates for which the Administration was noted. How successfully this was done, so far as transformation costs are concerned, is shown in Figure 14.

Rising price trends have been countered in the following ways:

1. Standardization and quantity purchases.
2. Use of larger units.
3. Use of lower basic insulation levels.
4. Use of autotransformation.
5. Use of forced oil cooling.
6. Use of modern compact designs to simplify erection and maintenance problems.
7. Use of mobile spares as stand-by for banks at many stations.

Standardization and Quantity Purchases

A rapid rate of growth has made possible quantity purchases of large transformers. Together with standardization of requirements, this has enabled manufacturers to spread design costs over a number of banks. The resulting interchangeability between stations has facilitated changes in plans, where required, to meet changes in the pattern of load growth. It also has made possible the use of one portable spare to serve several stations.

Most of the power generated at the Federal plants is transmitted to load centers at 230 kv and transformed to 115 kv by transformers designed to the following standards:

High Voltage—220 kv with two $1^1/_4$ per cent taps above and six $1^1/_4$ per cent taps below; nonautomatic load ratio control.

Intermediate Voltage—115.5 kv with taps at 117.88, 112.75, 109.75, 106.85, and 104.30; no load ratio adjuster.

Low Voltage—13.8 kv with reduced capacity taps at 11.5 kv; also at 4.02 and 9.78 for synchronous condenser starting.

Reactances are specified as follows:

For Transformers

High-low—16.5 per cent
High-intermediate—9.0 per cent
Intermediate-low—7.5 per cent

For Autotransformers

High-low—11.5 per cent
High-intermediate—4.0 per cent
Intermediate-low—6.5 per cent

Specified reactances are subject to a minus tolerance of 10 per cent. In the interest of system stability, they are

Paper 50-26, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 31, 1949; made available for printing December 27, 1949.

RICHARD F. STEVENS is Head Design Engineer with the Bonneville Power Administration, Portland, Oreg.

Figure 2 (left). Removing core and coils of a 25,000/33,333-kva forced air cooled transformer at J. D. Ross Substation for inspection

This was formerly considered a necessary step in erection of all large transformers after transcontinental shipment

Figure 4. Standard untanking tower showing railroad spur entrance

chosen to be as low as possible consistent with economical transformer design.

Standard bank capacities are:

75,000-kva self cooled; 100,000-kva forced air cooled

150,000-kva self cooled; 250,000-kva forced oil cooled

Future 75,000-kva banks also will be provided with forced oil cooling, giving them a maximum rating of 125,000 kva.

Two smaller banks, conforming generally to the foregoing standards, but with a self-cooled rating of only 50,000 kva each also have been installed. A few more smaller 230-kv banks also may be added in the future.

Five banks of 100,000-kva maximum rating have been installed to step down power from 230 kv to 13.8 kv to serve concentrated electrochemical loads.

Banks with capacities up to 37,500 self-cooled/50,000 forced air cooled are used for stepping down from 115 kv. Voltages higher than 230 kv also are under study for some lines. Both higher and lower voltage transformers, however, are beyond the scope of this paper, since present problems of very large transformers on the BPA system concern only 230-kv banks.

Figure 3. Standard untanking tower (front)

Size of Units

The use of larger capacity transformers, where feasible, will obviously decrease the transformation cost per kilovolt-ampere. This advantage becomes even more apparent when the cost of associated switching is considered.

BPA originally selected as a standard bank size 75,000 kva self-cooled (100,000 kva with fans). Six banks of this size, which were considered quite large at the time, were purchased during the first few years of operation. In physical weight and dimensions, the single-phase units of these banks approached the largest sizes which could then be handled easily by rail. In kilovolt-ampere rating, the banks matched roughly what was then considered to be a normal loading for a 230-kv circuit.

As loads and generation increased by leaps and bounds in the years that followed, it became apparent that it would be better to provide transformation in larger units. This had become feasible electrically because increased loads and generations put everything on a larger scale. It had become feasible from the standpoint of physical handling because improvements in transformer design had provided enormously greater capacities with little increase in size or weight. It was therefore decided to buy banks of double the old standard self-cooled rating—that is, 150,000 kva per bank. All 230-kv banks bought since 1944 have been of this rating. In the meantime, the practice of quoting a supplementary rating increase of $66^2/_3$ per cent of the self-cooled rating for forced oil cooling has been adopted by manufacturers. Transformers purchased in the last few years have been equipped with oil circulating pumps and can therefore carry 250,000 kva with these pumps running. In the meantime, necessity had forced the Administration to carry, and it had carried successfully, loads of this magnitude on its 230-kv transmission lines.

Thus the new standard bank size is relatively well matched to normal 230-kv line capacity on the basis of the new concepts of line loading.

Use of Lower Basic Insulation Levels

When design of the Bonneville system first got under way in 1938 and 1939, a decision was made to use 196 kv in preference to 230 kv as a switch and bus insulation level for 230-kv circuits. This resulted in considerable saving and has proved entirely sound in practice. In keeping with this decision, 196-kv bushings also were specified for all 230-kv transformer line terminals.

Serious consideration was given at the same time to use of this insulation level for the winding itself, but, because of lack of operating experience, a conservative viewpoint prevailed, and transformer windings for many years were required to be designed on the basis of full 230-kv insulation (1,050-kv impulse test). Subsequent experience and studies in our organization and in the industry at large have convinced the Administration that

Figure 5. Standard untanking tower showing transfer track door

Figure 6 (left). Transformer for Snohomish Substation

Unit of first 150,000/250,000-kva forced oil cooled 220-115-13.8-kv bank purchased by BPA. Is of form-fit type

Figure 8 (right). First step in uprighting Snohomish transformers, using jacks

this was much too conservative. In 1948, therefore, specifications were issued which permitted alternate bids on high-voltage winding insulation of the 196-kv class (900-kv impulse test). These alternate bids showed substantial savings and were accepted.

BPA, however, was not completely satisfied. It is common knowledge that existing voltage levels were set up for ungrounded systems, though such systems are virtually nonexistent in the higher voltages. Many utilities, like BPA, have taken advantage of the lower maximum voltage stress on their grounded neutral systems and have selected the next lower standard voltage level. However, because the steps between voltage levels are not uniform, the resulting factors of safety are largely hit or miss. It is felt that it would be more logical to determine insulation levels in a rational way for the far more common grounded systems. For instance, BPA feels that an impulse level of about 800 kv would be adequate for its 230-kv equipment, assuming proper application of lightning arrester protection, and intends to specify this level in the future specifications. The Administration is investigating the possibility of reducing the required level still further for some applications.

It is believed that this lower insulation requirement may bring substantial cost savings as compared to the 900-kv impulse level associated with the 196-kv class, even if no change is made in industry standards. It is felt that 230-kv transformers purchased by BPA are too large to be production line items, and yet are purchased in sufficient quantities so that design costs may be spread over many units. Obviously, still greater savings would be possible to BPA and other users if industry standards could be rationalized along some such line as this. The Administration, therefore, has lately taken an active part in discussions looking toward this goal.[1] This matter is discussed in more detail in another AIEE paper.[2]

Use of Autotransformers

For the capacities and insulation levels originally specified, cost comparisons showed little saving in favor of autotransformers as compared with the transformers actually purchased.

On the other hand, the autotransformers offered a little more difficulty in regard to protection and in application of tap changing equipment. Moreover, they did not provide any possibility for connecting the 115-kv winding in delta in-

Figure 7 (left). Transformer of Figure 6 mounted on side on low bed car for shipment

Figure 9 (right). Second step in uprighting Snohomish transformers, using cables

Figure 10. Snohomish transformer upright, ready for mounting wheels

stead of star to serve possible 69-kv loads.

When prices were taken in 1947, however, on much larger transformers designed for a lower (196 kv) insulation level, it was found that the savings were sufficiently large to outweigh any of the disadvantages. Autotransformers have since been standard for 220- to 115-kv transformation.

In addition to direct cost saving, the smaller weight and dimensions are a big factor in making it possible to handle units of greater kilovolt-ampere capacity with less elaborate facilities.

Use of Forced Oil Cooling

In common with most other utilities, BPA standardized at the start on self-cooled transformers for its substations with provision for $33^1/_3$ per cent increase in capacity by the use of fans.

During the war, when faced by the necessity of providing the most capacity with the least material, BPA purchased transformers with forced oil circulation. The first BPA bank with this type of cooling was installed during the war at Spokane, Figure 1.

Forced oil cooling now is standard on all new 230-kv transformers. In general, the basic rating is specified on a self-cooled basis, with neither fans nor oil circulating pumps operating. A supplementary rating $33^1/_3$ per cent higher than the basic rating is specified with fans in operation. Where forced oil cooling is specified, a rating $66^2/_3$ per cent higher than the basic rating is specified, in addition to the other two ratings.

An exception was made in the case of the rail-mounted spare which will be described later. To make possible a design meeting difficult space and weight limitations, this transformer was not required to operate with oil circulating pumps shut down. However, two oil pumps are provided and the transformer must be able to carry 70 per cent of its rating with one pump out of service.

Use of Simpler Handling Facilities

Recent improvements by manufacturers in transformer design have made possible a great saving in the cost of handling facilities.

Until recently it was the universal BPA practice to untank the core and coils from each transformer after it was delivered and before it was put into service. Transformers shipped from eastern factories to the west coast over the long rail routes apparently take tremendous punishment en route. At times it has seemed that the transformer which arrived completely undamaged was the exception, not the rule. Untanking has often disclosed serious damage that would otherwise have gone undetected. Thus some heavy lifting device was formerly considered essential for this purpose, Figure 2.

Some type of lifting device also was necessary to remove the shipping covers commonly placed on the large power transformers for rail shipment, and substitute the permanent top sections. A means of installing the heavy bushings also was required. Some shelter from the weather was desirable and essential where work could not be scheduled for favorable weather. With rains common through the fall, winter, and spring in the western part of the BPA area, and dust storms common in the desert sections, favorable weather could seldom be assured.

A standard building, Figures 3 to 5 inclusive, was therefore designed to handle such work at our larger stations. The main crane aisle is 35 feet 8 inches wide, 70 feet 8 inches long, and 45 feet high to top of crane rail. A 100-ton travelling bridge crane, electrically operated, is provided.

This aisle is served by a spur from the nearest railroad, and by an extension of the transformer transfer track which generally enter from doors on opposite sides. This provides a convenient means for unloading from railroad cars, for untanking transformers for inspection or repair, and for assembly and loading of the transformers on the transformer transfer truck for the final trip to the permanent position in the switchyard. The aisle provides good repair facilities in case of damage in service, and also convenient means for unloading and working on other heavy equipment.

Combined in the same building are an oil pump room, small shops, a storage area, loading dock, and offices.

Convenient as this building is for construction and maintenance, it represents a rather heavy investment which is idle much of the time. Until recently, however, this investment was felt to be almost unavoidable.

Considerable thought was given to simplifying the facilities, substituting perhaps a square tower with fixed hoist, or hoist with travel in one direction only. Unfortunately, studies of these alternate

Figure 12. Spare transformer bus

Where single-phase spares of the ordinary type are installed, special busses are mounted and connecting parts are made ready to facilitate quick electric connection of the spare if required, without moving it

Figure 13. Preliminary drawing of rail car mounted transformer recently purchased to serve as a common spare for several stations

Figure 14. BPA transformation costs, 1940 and 1949

1940 costs based on transformer banks rated 100 megavolt-amperes (forced air cooled); 230-kv insulation level; one spare transformer for each two banks and an untanking tower for each three banks. 1949 costs based on autotransformer banks rated 250 megavolt-amperes (forced oil cooled); insulation level reduced from 230 kv to 196 kv; one rail car mounted spare transformer and one untanking tower for each eight banks. Weighted cost of untanking towers and standard 1940 transformers has increased approximately 100 per cent

schemes seemed to show that the cost savings would not have been commensurate with the conveniences sacrificed, as compared with the design adopted.

Buildings essentially identical with the one shown in Figure 3 have been built at Chehalis, Midway, and Covington Substations. The crane aisle section is essentially a duplicate of the crane aisle that forms part of the much larger building at J. D. Ross, and also of the crane aisle that was designed as part of the control house at Longview.

Restrictions on building construction imposed during and immediately following the war discouraged building of untanking towers at some of the later stations, such as the one at Spokane. At Snohomish, funds were not available in time to complete a building before the delivery there of the first large 230-kv transformer.

Fortunately, advances in transformer design had by then made it possible to ship even very large transformers completely assembled, except for bushings. The first such transformers purchased by BPA for Snohomish were of the so-called form-fit type, and were shipped lying on their sides. Our riggers had no particular difficulty in upending these on arrival, using the method illustrated in Figures 8, 9, and 10.

Some concern was felt about putting a transformer into service without direct inspection of the condition of core and coils after arrival. The manufacturer assured us, however, that this was unnecessary and results so far have confirmed this opinion.

A transformer bank of the same electrical capacity, make and type, has been ordered for the new 230-kv substation at Olympia, Wash. It is somewhat smaller in physical size, since the 115 kv is obtained from an autotransformer tap instead of a separate winding. It is proposed to install this bank in the same manner as the Snohomish bank, and the untanking tower originally intended for Olympia has been indefinitely deferred, with a resulting substantial cost saving.

Four other 150,000/250,000 kva autotransformer banks, electrically identical with the Olympia bank, also have been ordered. The first of these will be installed in the new 230-kv Goshen Substation near Eugene, Oreg. It will be of a different make and of the core type. It will be relatively wide and long in plan view and short in height, so that it will be possible to ship it mounted erect on a low-bed car. The manufacturer of this transformer bank claims that it also will be built and braced to avoid the necessity of untanking for inspection after delivery. The construction of an untanking tower at Goshen, therefore, also can be avoided or deferred.

Three other autotransformer banks of this size have been ordered which will be of a still different make. Although exact size and shape of these are not yet determined, they too will be suitable for erection without untanking.

Because of the size and weight of equipment involved, considerable effort has been taken to locate 230-kv stations where they could readily be served by spurs from existing railroad lines. Of 11 230-kv transformation stations in operation or under construction, only two are not so served. A 100-ton trailer, nicknamed "the jeep", Figure 11, was purchased for transporting transformers from the nearest railroad spurs to the 230-kv substations which have no spurs of their own.

Where indoor handling facilities are provided, the spur track enters one side of the building or the end, while a transfer track leaves the building from the other side and extends into the substation yard.

The transfer tracks are laid with the rails at the approximate level of the general yard grade. The transfer track rail gauge at all stations is 9 feet $7^{3}/_{8}$ inches. At some stations the railroad spur is centered on the same line as the transfer track, and the standard gauge rails are extended into the yard between the wide gauge transfer track rails, on the same ties. This permits flat cars and low bed cars with equipment to be unloaded as near as possible to the footings where the equipment will be installed.

Because of the plan to use a rail car mounted spare, this arrangement will be necessary at all 230-kv stations in the future in order that the spare can be moved into place quickly. Extensions and changes in spur tracks at existing stations will be made when and if feasible to provide this feature.

For the ordinary moving of transformers within the station, a standard transfer car is provided. This is designed with wheels set for our standard transfer track gauge of 9 feet $7^{3}/_{8}$ inches, and supports rails at right angles with a rail gauge of 6 feet 8 inches to suit the standard wheel gauge. These rails are 2 feet $2^{3}/_{8}$ inches

higher than the top of the transfer track rail, to match the standard elevation of the rails which support the transformers on their concrete footings.

It is planned to build in the future only such additional untanking towers and associated shops as are needed to make such facilities available at strategic centers in the region. They are no longer considered to be necessary at all major 230-kv stations.

Economical Application of Spare Transformers

Until recently, the Administration has sought to provide spare transformers at all major stations where the supply of the load is dependent on a single bank, and at some stations with more banks if the load is such that a prolonged outage of one bank would be disastrous. Often, however, this insurance could not be provided, either from lack of funds, or (as during the war) because of material shortages. In fact, it was necessary during the war to combine the station spares from Chehalis, Ross, and Covington to make up a much needed second bank at Covington.

Where spares have been used, it has been standard BPA practice to install bus work to permit rapid connection of the spare, in place of a faulted transformer in any phase, without physically moving either, in order to decrease the outage time, Figure 12.

Permanently mounted bus work for 230, 115, and 13.8-kv connections is installed to the extent which is feasible without interference with the regular bank wiring. Pre-cut cable and pipe bus connections are made up and stored against the day when they may be needed for connecting the spare transformer.

The cost of the insurance premium which spare transformers represent is high. In the case of BPA, the justification must rest entirely on judgment, since no accurate data exist on transformer life expectancy. There have been no failures whatsoever on BPA power transformers in service. A 40,000-kva transformer was recently untanked after about nine years of service, during much of which time it carried overloads exceeding 100 per cent. No signs of insulation deterioration could be detected. However, unlikely as a service failure of a transformer may be, the consequence of a prolonged outage, if it should occur with no spare available, might be very serious indeed.

A new approach to this difficult problem was taken in 1949 with the purchase of a rail car mounted spare, which is to be delivered in 1951.

This is to be a single-phase 83,333-kva 220-to-115 kv autotransformer, with standard electrical characteristics and load ratio control equipment, so that it can be substituted for a single-phase unit of any of the large 220-to-115 kv banks recently purchased. A special separate 57.1-kv winding also is provided so that it also can serve as a spare for the 220 to 57.1 kv bank at Troutdale substation.

Figure 13 shows the general design and approximate dimensions of the unit. Weight and dimensions are such as to insure that it can be shipped from eastern points to the Bonneville area over any of the main transcontinental lines or readily shifted between points within the area.

Forced oil circulation, with two pumps, is provided. To permit saving of size and weight, no self cooled or forced air cooled rating was specified, but the unit must be able to carry 70 per cent of its full rating with one pump shut down.

The spare can be removed from the car, if desired. BPA has often encountered troubles and delay in moving transformers from one station to another, due to the inability of the railroad lines to supply low bed cars promptly. It has frequently been necessary to pay demurrage charges for holding cars which had been used in shipping transformers from the East, until they could be used for some transformer move on the BPA system. In the future, it will be possible in such cases to unload the spare and use its low bed car for shipping a transformer between stations or to the factory for repairs.

The first rail car mounted spare will be kept normally at some central point on the BPA system, probably at Vancouver, Wash. It will serve as a spare for eight transformer banks existing or on order.

It is expected that as other banks are installed, additional rail car mounted spares will be added so the ratio of one spare to about eight banks will be roughly maintained. With the purchase of more spares, the average length of rail haul will be decreased. It seems likely that there may be three of these on the system by 1958, located at strategic points to serve the northwestern, southwestern, and eastern portions of the system, respectively.

The railroads have assured the Administration that a special train can be made available on two hours' notice in case of an emergency. While the transformer is being shipped to the station involved in the trouble, crews at the station can be disconnecting the faulted transformer and connecting the spare transformer busses to the phase affected. When the spare arrives, the transformer and car will be spotted in front of a specially equipped spare position with facilities for making connections quickly to the spare transformer busses. The transformer will then be rotated 90 degrees on the flat car, moved into position on the footing, and connected.

Actually, the complete lack of failures in service of any of the BPA power banks makes us hope that actual use of the rail car mounted spares, and of other spares now on the system, will be limited to scheduled maintenance. They will, however, be ready for use if required, at an investment cost less than one quarter of the amount which would have been required to provide separate spares for each station.

Discussion

P. L. Bellaschi, Consulting Engineer, Portland, Oreg.: The strides in the application of 230-kv power transformers, related in the paper, were made possible through engineering of a high order combined with a well-co-ordinated and progressive approach to the over-all problem. Reduced insulation proportioned to the requirements of grounded-neutral operation, the advent and application of forced-cooling, utilization of autotransformers, in addition to advances in constructional features and in the basic materials used, all have contributed their part to a more effective equipment and to reduced size and weights. These advances combined have facilitated the design and shipment of complete units for 250,000-kva banks required to match present-day capability of 230-kv transmission lines, another advance in the art realized concurrently in the course of these developments. Finally full advantage has been taken of the increased reliability of the equipment and diversification made possible through system development, to reduce field installation equipment and transformer spares down to a new acceptable minimum.

The economical gains achieved are eloquently in evidence in Figure 14 of the paper. The question might then be raised as to

whether similar advances can be anticipated in the years to come in view of the extent of rationalization hereto achieved. Without speculating on the future, fundamentally certain facts stand out and are well to consider. For instance it is a fact that about one-half of the cost in present-day high-voltage transformer apparatus is accounted for by the insulation alone. Therefore this would appear as a fertile field for future investigation and study both in the design and application of the equipment. Again to consider another possibility, it is a fact that thermally insulation is the limiting factor which determines rating, permissible overload, and useful life of transformers. Advances that would permit higher operating winding temperatures would be a contributing factor towards more economical transformation costs. One could speculate further on possibilities, but one point is clear.

It is a foregone conclusion that continued progress in this field will call for sustained and co-ordinated effort in the years to come directed both to the development of the design proper and to further rationalization regarding the application of the apparatus in the field.

W. Gordon James (Westinghouse Electric Corporation, Sharon, Pa.): The author of this paper is to be complimented for his very timely and interesting treatment of the application and handling of very large power transformers on the system of the BPA.

Obviously the key note of the information presented in this paper is "economy."

Since I am a tax payer and also a designer of large power transformers such a key note certainly strikes a responsive chord.

Truly, "economic engineering is good engineering" and conversely, "good engineering is economic engineering" and surely the larger the kilovolt-ampere ratings and the higher the dynamic operating voltages become the greater the need for over-all economics such as specifically outlined in this paper.

The engineers of the BPA have contributed greatly to the over-all advancement of the art of large, high-voltage power transformer design and application by virtue of their knowledge and understanding of the problems confronting designers of such equipment as evidenced by their cooperativeness as regards design and application limitations as well as the constructive assistance they render to standardizing bodies whose objectives are to utilize to a maximum degree all developments of the art, consistent with over-all economics, and best engineering, to the end that long trouble-free service will be a natural result.

It also might be observed, without detracting from or minimizing this paper or the accomplishment of the BPA, that large power transformer manufacturers also have contributed heavily in making such economics possible through years of intensive research, at no little cost, to improve materials, methods, and processes whereby such application economics, as described in this paper, are possible.

Speaking for at least one manufacturer I believe, from many years of experience with the design and application of large high-voltage transformers, that the confidence placed in current power transformer design practice is very sound and well placed. Certainly the use of greater standardization, larger units, lower basic insulation levels, autotransformers, forced-oil cooling, more compact designs, and the reduction of capital investment in separate bank spares by the use of a mobile spare are, in general, sound practices and will result in great savings economically, provided, of course, that all these factors are properly co-ordinated with the requirements of the system.

Since, from an application and handling standpoint each of these items have been very adequately discussed in this paper I will not, in conclusion, comment further except as regards the use of lower basic insulation levels.

Although great strides have been made in recent years as regards insulation structures and protective equipment, making it possible to realize appreciable economics by using reduced basic insulation levels, further reductions should be approached with caution and only after a complete system study fully co-ordinated with the protective ability of protective equipment.

Richard F. Stevens: I agree heartily with Mr. James that great credit is due to the manufacturer for advances made in transformer design. I join Mr. Bellaschi in the hope and belief that still further advances may be expected. It is on these that we must depend, to a large degree, in keeping down our transformation costs.

Side by side with this goes the work of the utility application engineer. He must study his own system, consider all hazards, evaluate the effectiveness of protective equipment, and avoid unjustified risks on the one hand, and unjustified expenses on the other.

In passing, it might be pointed out that Mr. James is not strictly correct in inferring that he is directly affected as a taxpayer by what we pay for equipment, since all such costs must be returned from the sale of power.

The responsibility still exists, however, for economy as a means of maintaining the lowest possible electric rates. I believe that my paper shows, and the two discussions recognize, that this responsibility is being taken very seriously by the BPA engineering staff.

Liquid Cooling of A-C Turbine Generators—Part II

CARL J. FECHHEIMER
FELLOW AIEE

IN A previous paper[1] presented before the AIEE in 1947, a combination of three cooling media was advocated for large turbine generators: oil (or equivalent synthetic liquid) for the stator, water for the rotor, and hydrogen for the internal surroundings of the stator and rotor. From the thermal standpoint, this combination is believed to be superior to any other.

The opinion has been expressed, however, that complications are involved.

For simplification, the following now are proposed:

1. For small and medium-rated generators, the coolant in the ducts to be water for stator and rotor, with air in the internal surroundings. For the large machines, the coolant in the ducts to be water for stator and rotor, with hydrogen in the internal surroundings. The complications associated with oil for the stator are eliminated, as are also the complications associated with hydrogen for small and medium-size machines. The coil ends for both stator and rotor would be cooled by the internal gas, suitable small internal heat exchangers being provided.

2. All internal water systems could be hydraulically paralleled externally, and one external heat exchanger, circulating pump, and so forth, could be used for all, operation being in closed systems for each internal branch.

3. The external deaerator is to be omitted, as it was found by tests on the hydraulic model of the turborotor, to be unnecessary, as described in this paper.

4. The small ducts below the main slots in the rotor are to be omitted, as further calculations indicate that the water in the teeth ducts provides ample cooling, and the temperature drop in the steel is still reasonably low.

Other simplifications, most of which were brought out in the earlier paper mentioned above, are:

5. Omission of internal fans.

6. Omission of the large internal heat exchangers. Small internal heat exchangers would be needed for the gas for the coil ends. One external heat exchanger would be used for most of the losses.

7. Omission of vent ducts for the stator and rotor. Water cooling ducts are to be substituted for them.

8. Omission of ducts for coolant flow to and from the internal heat exchanger.

Commenting on item number 6, the heat flow in the external heat exchanger is from water to water, instead of from hydrogen (or air) to water. Therefore heat exchanger size will be considerably reduced. The frame diameters of hydrogen-cooled machines are much larger than they would be with liquid cooling because the gas to water heat exchangers must be placed internally, and the external diameters of the stator cores are appreciably larger. As the frame and end bells of a hydrogen-cooled machine are made to withstand an explosion, a large frame diameter is costly. Also, the external heat exchanger tubes need not be provided with rather costly fins, as needed with hydrogen or air.

This paper is divided into four parts: construction of the stator for water cooling; calculations of relative ratings as affected by the cooling media; hydraulic model of a liquid-cooled turboalternator rotor; and mitigation of Coriolis' forces.

Water-Cooled Stator

A longitudinal section of a water-cooled stator and rotor is shown in Figure 1. Two alternative schemes for the stator are shown in transverse section in Figures 2(A) and (B). Square or rectangular metal tubes are used, through which water (treated with a corrosion inhibitor) flows, instead of the usual vent duct spacers, but now the cooling is effected only through the water in the tubes. These tubes serve the dual purpose of cooling and of supporting the longitudinal pressure of the laminations. In Figure 2(A) additional supports are provided, but in Figure 2(B) the spiralled tubes in the core portion afford ample cooling surface and may be made to provide adequate support. The arrangements indicated in Figures 2(A) and (B) afford effective means for transferring the generated heat in the tooth-slot and core zones in accordance with the loss density therein. The designer can readily determine the number of tooth-zone tubes to connect in series, the losses having been calculated.

For the rotor and stator coil-ends, gas streams pass between consecutive coils. The high centrifugal forces are ample to secure adequate volumes of flow. High velocities at the coil surfaces are insured by suitable blocking for both the rotor and stator coil ends. Although such high velocities reduce the volume of flow slightly, the gain in velocities insures the relatively high heat transfer rate needed.[2] Calculations indicate that it is then possible to secure about the same temperatures as for the embedded copper, with water in the rotor ducts. It has been claimed for the present-day hydrogen-cooled rotors that lower coil-end temperatures are obtainable with the rotor blocking than for the ventilated embedded parts.[3] For the stator coil ends, with their thick walls of insulation, the external surface heat densities are much lower than for the rotor, and sufficiently low temperatures should be obtainable.

Paper 50-28, recommended by the AIEE Rotating Machinery Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 20, 1948; made available for printing December 12, 1949.

CARL J. FECHHEIMER is a Consulting Engineer in Milwaukee, Wis.

The author acknowledges the helpful suggestions of K. L. Hansen, E. F. Vilter, Dr. J. F. H. Douglas and several Allis-Chalmers engineers. He also thanks the Milwaukee School of Engineering for facilities and aid in testing, in particular Fred Wutschel of the school's faculty.

Figure 1 (left). Water - cooled stator and rotor. Longitudinal section

Figures 2 (A) and (B) (right). Water - cooled stator. Transverse section

As shown in Figure 1, the coil-end gas streams pass through suitable internal stationary heat exchangers. A stationary disk (attached for convenience to the exchanger's inner side) prevents the pressure generated by the rotating rotor end disk from interfering with the radially inward gas flow.

Relative Ratings

All large turboalternators, supplying loads for which the current lags the voltage, are limited by rotor copper heating. In this study the rotor ampere turns, for a given temperature rise, are compared, for various cooling media.

The following are considered to be the same for any two rotors that are to be compared:

(1) Number of poles and frequency.
(2) Thickness of, and materials in, insulation wall.
(3) Slot dimensions, their number and spacing.
(4) Rotor diameter.
(5) The steady-state average copper temperature.
(6) Space factor of copper in a slot.
(7) Specific resistance of the rotor copper.

These seven items are the same, but the cooling media are changed. In general, the cooling ducts for liquids are narrower than for gas, but that does not affect the derivation and conclusions.

List of Symbols

A = cross section of one rotor conductor, square inches
C = number of rotor conductors per slot
d = depth of rotor slot below wedge, inches
D = rotor external diameter, inches
I = rotor amperes per conductor
K_1 = coefficient for temperature drop through wall of slot insulation
= approximately thermal conductivity of wall, watts/inch times degrees centigrade
K_2 = coefficient for all other rotor temperature drops, watts/square inch times degrees centigrade
K_3 = space factor in rotor slots = $(CA)/(Sd)$
n = number of rotor slots per group
p = number of poles
S = width of rotor slot, inches
t = thickness of single wall of rotor insulation, inches
θ = total mean temperature rise of rotor copper, degrees centigrade
θ_1 = temperature drop through wall of rotor insulation
θ_2 = temperature drops other than θ_1 (so that $\theta = \theta_1 + \theta_2$)
ρ = specific resistance of rotor copper, ohms per inch cube
τ = pole pitch on rotor periphery, inches

The total temperature rise of the copper is

$$\theta = \theta_1 + \theta_2 = \left(\frac{\rho CI^2}{A}\right)\left(\frac{t}{2(s+d)K_1} + \frac{pn}{\pi D K_2}\right) \quad (1)$$

Substituting for $A = K_3 Sd/c$ and $\pi D = \tau p$ and solving,

$$CI = \sqrt{\frac{\theta K_3 sd}{\rho}}\sqrt{\frac{1}{\dfrac{t}{2(s+d)K_1} + \dfrac{n}{\tau K_2}}} \quad (2)$$

The rating is evidently proportional to the ampere conductors per slot, CI. Suppose that, in one combination of coolants, the rotor is operated in certain gaseous surroundings, the coolant in the ducts being separately defined, which combination is referred by subscript I. These ampere conductors are to be compared with those of another combination for which subscript II applies. All quantities under the first radical in equation 2 are the same for the two combinations, and it therefore drops out in the comparison ratios

$$\frac{(CI)_I}{(CI)_{II}} = \sqrt{\frac{t\tau(K_2)_{II} + 2n(s+d)(K_1)_{II}}{t\tau(K_2)_I + 2n(s+d)(K_1)_I} \times \frac{(K_1)_I(K_2)_I}{(K_1)_{II}(K_2)_{II}}} \quad (3)$$

Generally, with liquids, the ingoing temperature is lower than for gases, and as the maximum temperature is the limitation, the allowable temperature rise, θ, with liquids should be greater than with gases, thereby making the rating ratio even more favorable for liquids than given by equation 3.

The ratio of ratings is then dependent upon the coefficients K_1 and K_2, and somewhat upon the choice of slot proportions. The determination of the coefficients now will be given.

From laboratory tests on transverse thermal conductivity of mica plate in air, the composite's thermal conductivity was found to be about 0.003 watt/inch times degrees centigrade. To arrive at numerical values for the ratio in equation 3, the slot lining in a turborotor is taken as 0.0625-inch thick, and the area per inch axially through which the heat flows is the arithmetical mean between the slot surface, 2 $(S+d)$, and the copper surface. For simplicity, in the above, the surface per inch axially is taken as $2(S+d)$, and as such surface is about seven per cent more than the mean, the equivalent transverse conductivity becomes $K_1 = 0.003/1.07 = 0.0028$.

In an atmosphere of hydrogen most of the air particles in the slot liner are supplanted by hydrogen, the thermal conductivity of which is about seven times that of air. Experiments indicate that the composite's conductivity is thereby approximately doubled, and consequently has been taken as 0.0056.

From a large number of tests on ventilated turborotors in air, the average value of K_2 was found to be about 0.083 watt/square inch times degrees centigrade. Comparisons with data from Luke's paper[4] on a revolving cylinder (plotted on log-log paper) show somewhat greater values. (At such high peripheral velocities the heat transfer rate does not change much with the speed.) The difference between the two probably is because the air windage loss augmented the temperature of the actual rotor more than for Luke's model; the internal drop in the steel in the actual rotor increased the copper temperature and such drop was zero in the model; and also because of heating of the air and inequalities in distribution of air in the radial vents which produce inequalities in copper temperatures. K_2 will be taken as 0.083 for air.

The heat transfer rate with hydrogen at one atmosphere is about 1.46 times that

of air at one atmosphere. With hydrogen, the windage loss does not augment the temperature appreciably, but the internal drop in the steel would be the same as for air for the same flow of heat; in hydrogen, with larger heat flow, this drop is greater. One of these would have the effect of increasing the coefficient K_1, and the other of decreasing it. It is believed that very little error is introduced by taking K_2 for hydrogen (at one atmosphere pressure) to be 1.46 times that for air, that is, 0.121.

For hydrogen at two atmospheres pressure, the heat transfer rate from the surface is approximately $(2)^{0.8} = 1.74$ times that for one atmosphere. However, with the larger heat flow in the steel, there would be lower cylindrical surface temperature for a given internal copper temperature, which means less heat transferred for a given internal temperature. Again, for simplicity, take it to be $(1.8)^{0.8} = 1.6$ times that at one atmosphere, or 0.193 watt/square inch times degrees centigrade.

Several rotors were calculated with water in rectangular ducts. In such cases, when the I^2R loss is referred to the rotor's cylindrical surface, the total drop beyond the wall of insulation gave an equivalent K_2 of approximately 1.0 watt/square inch times degrees centigrade, or more, for the larger rotors, and 0.85 for the smaller. This took account of the water's mean temperature rise, the drop in the teeth, and the drop at the surface of the ducts.

In Table I, a combination is defined by the surrounding fluid; the pressure of that fluid; and the fluid in the ducts. The ratios were obtained by substituting the values of K_1 and K_2 in equation 3 for two combinations that were to be compared, and these ratios will be found in column 7.

For large rotors, the preferred combination is surroundings of hydrogen at one atmosphere pressure and water in the ducts. For medium and smaller ratings, it is believed at present to be desirable to operate in an air atmosphere with water in the ducts, thereby reducing the complications associated with hydrogen. All items in Table I, except items 8 and 9, pertain to large ratings, (usually of the order of 100,000 kva) and 8 and 9 apply to about 10,000 kva.

Comparing the hydrogen surroundings and water in ducts combination with air, for both, items 1, 8, and 14 show rating ratios of 2.06, 1.91, and 2.19, for different slot combinations. Now comparing the hydrogen-water combination with hydrogen-hydrogen at one atmosphere pressure, items 2, 10, and 11 show ratios of 1.62, 1.74, and 1.695, a very considerable gain.

Comparing operation in air surroundings and water in the ducts, with air for both combinations, items 7 and 9 show ratios of 1.54 and 1.42. Thus, by running water in the rotor ducts in a medium-rated generator an increase of 42 per cent in rating is obtainable.

Comparing hydrogen surroundings and water in the ducts with hydrogen at two atmospheres, as now used in large generators, the rating ratio is 1.39, item 3, again a considerable gain over the most favorable cooling medium used at present. Experience has indicated that operation in hydrogen at one atmosphere pressure permits increasing the rating by 25 to 30 per cent as compared with operation in air. For the first slot combination, the calculated ratio is 1.27, item 4, and for two other slot combinations it is 1.26, items 12 and 13. Experience has further indicated that the rating can be increased about 17 per cent by changing from one to two atmospheres of hydrogen. The calculated ratio in item 5 is 1.164. The agreements between experience and calculations are striking.

It is believed that the rating ratio of hydrogen-water over air-air, such as items 1, 8, and 14, or over hydrogen-1-hydrogen, items 2, 10, and 11, are even greater than given, because:

1. With more favorable heat transfer in the heat exchanger, the ingoing ambient temperature is lower with water as a coolant than with air (or for that matter, with hydrogen).

2. The rotor copper temperature is more nearly uniform with water in the ducts than with air (or with hydrogen), and therefore the maximum copper temperature is lower for a given average temperature. It is believed that the maximum, not the average copper temperature should be the criterion for rating.

3. The lower windage loss in a hydrogen atmosphere as compared with air means lower surrounding gas temperature. (Of course this does not apply to the comparison with the hydrogen-cooled machine.)

However, the rating ratios in the table do not bring these into the picture. For the large ratings, less costly steel generally may be used in the rotor, owing to lower stresses associated with smaller diameter rotor.

HYDRAULIC MODEL OF LIQUID COOLED TURBO ROTOR

Figure 4. Longitudinal section of model

Figure 5 (left). Intake end of stationary model

Figure 6 (right). Discharge end, running at 3,560 rpm

Hydraulic Model of a Liquid-Cooled Turboalternator Rotor

The construction and tests of a hydraulic model were undertaken chiefly to dispel the fears of those who doubted that a liquid could be passed through a high-speed rotor without giving trouble.

The model was driven direct by a 2-pole 60-cycle induction motor at nearly 3,600 rpm. Figure 3, reproduced from part I of this paper,[1] is a longitudinal section of a liquid-cooled turboalternator, and Figure 4 is the longitudinal section of the model. Corresponding parts in Figures 3 and 4 carry the same letters. A comparison reveals the close similarity between model and prototype. A few departures are given herein. Figure 5 shows the intake end of the model at stand still, and Figure 6 the discharge end, running at 3,560 rpm., and discharging approximately 55 gallons per minute. Figure 7 shows some internal parts of the model, and Figure 8 is a diagram of the model's external hydraulic system.

The liquid used was water plus a suitable corrosion inhibitor, operation being in a closed system. The losses were so small that no heat exchanger was needed.

The Inlet End

The water enters through the stationary pipe *A-B*, Figures 3 and 4, located in the hollow rotating shaft, then flows radially outward in ducts *F* and in the casing *H*. In the generator there may be a radial channel for each tooth which joins the casing with a longitudinal duct *J* in the teeth. (The junction is shown sharp in Figure 3 and rounded in Figure 1. This is considered further under mitigation of Coriolis' Forces.) In the model these ducts are replaced by 16 seamless tubes, 1-inch external diameter bent to semicircles, shown in Figures 4 and 7. The resistance to flow offered by the long generator duct was simulated in the model by resistance orifices, one for each tube. The hood surrounding the 16 seamless tubes was put on solely to reduce the windage loss, which was found, from wattmeter measurements, to be low.

The Discharge End

The left end of the generator's rotor body is nearly similar to the right end, the liquid flowing radially inward to the hollow shaft *L*. After flowing axially through *L*, the water flows radially outward through symmetrically spaced holes *M*, terminating in the discharge orifices, located close to the outer shaft diameter. In the model, a 12-inch diameter cylinder was pressed on the hollow shaft, 12 inches being about the shaft diameter needed to transmit the torque for a large 3,600-rpm generator. Four holes, *M* in the model, constitute a centrifugal pump, and they are the principal means for producing the flow of liquid. In Figure 3 these holes are shown curved adjacent to the shaft bore, but to simplify manufacture they were tapered in the model, which apparently reduced the shock loss sufficiently. Plugs were screwed into the cylinder adjacent to its outer periphery, with small holes, only 7/32-inch diameter, or 0.15 square inch for all four. Without allowing for stream contraction (vena contracta), the velocity through these orifices is 118 feet per second at cylinder peripheral velocity of 185 feet per second, and yields a flow of 55 gallons per minute.

The Discharge-Collecting Chamber

After discharge from the orifices into the stationary inner collecting chamber *N*, some liquid passes through holes in the cylinder separating the two collecting chambers.* The remaining liquid passes between stationary ribs and the shaft (or the model's 12-inch cylinder), into another inner collecting chamber *N'*, where under the action of the centrifugal forces from the rings *X*, most of this remainder is discharged through holes into the outer collecting chamber. The liquid is drained from the outer collecting chamber to the sump through drain 4, Figures 4 and 8. What little liquid is left should be carried to the sump through small drain 3 from which there was a trickle in operation. There are no rubbing seals. In the model, the side plates are slightly smaller at their inner diameters than the 12-inch cylinder. It is suggested that, in a generator, the part of the shaft enclosed by the collecting chamber be slightly larger in diameter than the adjacent parts, to compensate for the weakening due to the holes *M* and the holes for the orifice plugs.

During the passage of the liquid through the rotor, the centrifugal action thereon between the hollow shaft and the rotor ducts at the right end is balanced substantially by that at the left end. However, the head generated in the discharge holes *M*, functioning as a centrif-

*The outer collecting chamber is not shown in Figure 3 but is shown in Figure 4. In an actual machine the construction should be either like the model or should have additional sets of stationary and rotating ribs to insure against leakage. The parts should be machined and the two halves doweled; it then may be possible to secure leakless operation without more ribs. Figure 7 shows the collecting chamber with the upper part raised.

Figure 7. View of some exposed parts of model

ugal pump, is not balanced. Such head is considerable and appears largely as static pressure just below the discharge orifices, where it is converted into velocity head.

The Catch Basin at the Inlet End

This also is a departure from the construction in Figure 3. A nonmetallic ring is of such internal diameter that it clears the pipe *A-B*. This decreased the leakage, and most of the water that got past the ring escaped from the catch basin through drain *1*. The rotating ring between the two stationary disks serves to throw off the water, which is drained to the sump through drain *2*. There was no external leakage, and there are no rubbing seals. No doubt the resistance offered by the outside of the stationary pipe *A-B* and the inside of the rotating hollow shaft, causing the water to move in a spiral, also reduced the amount of liquid drained off.

Operation of the Hydraulic System

The setup is shown schematically in Figure 8. The water level in the elevated tank is only seven feet above the model's horizontal center line, and produced a pressure of about three pounds per square inch at standstill of the model and two pounds per square inch when running. The purpose of the elevated tank and sump is to secure two separately functioning systems which operate together in series in a closed system. Otherwise, with two centrifugal pumps in series, there would be likelihood of surging.

When starting, valves *1* and *3* are closed and *2* is opened to prime the pump. Then *2* is closed, the pump is started, and valve *3* is partly opened to fill the tank, the overflow assisting in maintaining the water levels. Then the model is turned over slowly by hand and valve *1* is opened. The model then is brought up to full speed, valve *3* being opened sufficiently to keep the tank full.

At full speed the volume of flow is determined largely by the centrifugal head generated in the holes *M*. With the small inlet head and with loss of head between *E* and *L*, the pressure in the hollow shaft near discharge is probably below atmospheric pressure. It is conceivable that this reduced pressure might affect the volume of flow. The drops in pressure between entrance and the shaft bore *L* can be reduced by beveling or rounding the various ducts when the liquid enters them; also by making the liquid rotate just before it leaves the enlargement *E*, at an angular velocity approaching that of the shaft. One way of accomplishing this is to rifle the bore of the hollow shaft. Raising the tank level also would raise the absolute pressure in the shaft bore *L*.

Some air was absorbed by the water as it discharged from drain *4*. The partition was included in the sump to prevent air entering the small pump and causing it to lose its priming. In a generator the drain pipes should be submerged; no partition then would be needed in the sump. Bubbles rose at times in the eudiometer, showing that the pipe *P* served a useful purpose. Descriptions of other interesting phenomena are omitted for brevity.

Figure 9. Section of rotor intake duct with guide vanes

Generator Rotor Losses and Water Temperature Rise

According to design calculations of a liquid-cooled generator, rated 100,000 kva., 85 per cent power factor, 3-phase, 3,600 rpm, with 0.81 short-circuit ratio, the total rotor I^2R loss is about 334 kw, with 254 kw loss in the embedded parts. If 55 gallons of water per minute are to absorb these 254 kw, the water temperature rise would be 17.6 degrees centigrade. The 80-kw loss in the coil ends

Figure 8. Model's external hydraulic system

would be taken up by the circulation of hydrogen, as described elsewhere. The hydraulic losses, most of which are in the internal centrifugal pump M, were found from measurements with a polyphase wattmeter in the driving motor circuit of the model to be 11.7 kw, which would cause the water temperature to rise 0.8 degree centigrade more. These losses appear mostly after the water has absorbed the rotor loss.

It may be desirable, to secure somewhat uniform temperatures longitudinally in the rotor copper in such a large generator, to reduce the water temperature rise by increasing the rate of flow. To secure a short-circuit ratio of about 0.81, with the large number of ampere-turns, a long air gap is necessary. The loss in the rotor surface due to tufting of flux from the stator teeth is very small. With a long air gap those stray losses (with balanced stator currents) appearing in the rotor surface are of little consequence. Also, when operated in a hydrogen atmosphere, the windage is small, and much of that loss is taken care of by the circulating hydrogen. Therefore, the only losses considered as affecting the rotor temperature rise have been the rotor I^2R. With the smaller ratings, for which an air atmosphere is proposed, the conditions are similar to the large machines with hydrogen.

In the discussion of the previous paper[1] it was stated that water cooling had been tried (the Parson's scheme) in 1915. One trouble was that air got into some ducts and caused bad mechanical unbalance. After the model had been balanced without water, there was no trouble with unbalance after water was admitted.

Mitigation of Coriolis' Forces

As may be found in various publications, the Coriolis' acceleration is given by the vector: $2\ (dr/dt)\times\omega$. For the liquid cooled rotor, (dr/dt) is the radial velocity of the liquid with respect to the rotor, and ω is the angular velocity. Multiplied by the mass density, this acceleration then gives the force per unit volume of liquid. With the relative flow in a radial direction, these forces are tangential.

At the entrance to the longitudinal ducts J, with sharp corners, suppose that a small volume of liquid turns the corner, and then flows axially. The velocity in the radial supply duct diminishes from the position at the bottom of the longitudinal duct J to the top thereof. Unequal tangential Coriolis' forces are produced which would cause the liquid to whirl just before entrance to J. At the exit end the phenomenon would be similar, but the sense of rotation of the whirl would be opposite. Such whirls would seriously obstruct the liquid flow.

In the model with the 16 curved tubes J, apparently the flow was not impeded by such whirls, as the flow was large. Evidently, if each tube had a straight portion longitudinally between two curved ends, there would not be any diminution in flow due to Coriolis' acceleration. Consequently, in an actual machine, if suitably curved tubes were used at each end, the harmful effects of the whirls would be eliminated. As such tubes would probably be of rectangular section (instead of circular, as in the model), and generally of unfavorable aspect ratios, they can conveniently be provided with curved guide vanes, as has been found very beneficial for stationary elbows. (An excellent article on reduction of losses by means of guide vanes is by Loring Wirt[5].) One of several suitable constructions is indicated in Figure 9.

Considering the casings H, on the side in which the liquid flows outward, as it leaves the holes F, it is moving in space at the tangential velocity corresponding to the outer diameter of the holes F. As the liquid moves outward in H, its tangential velocity would have to increase if it is to flow in radial paths (with respect to the rotor). The inertia (Coriolis) forces then would cause the liquid to fall back, with respect to the rotor, and thereby to flow in circumferential paths in opposition to the direction of rotation. With respect to outside space, it would move in the same direction as the rotor, but with reduced angular velocity. As this circumferential flow would interfere seriously with the desired radial flow, it is prevented by means of radial partition plates so that the liquid flows in radial paths (with respect to the rotor) as if there were radial ducts throughout.

On the return side the liquid flows radially inward, and the circumferential velocity tends to be in excess of that of the adjacent parts; that is, it moves at greater angular velocity in space than the rotor. Again partition plates are needed to prevent harmful circumferential flow.

When constraints cause the liquid to flow in prescribed paths, the Coriolis' forces produce pressure against the walls, all the way from the bore of the hollow shaft to the outermost radius of the radial ducts. On the outgoing side they act against rotation, and on the ingoing side with rotation; thereby torques are produced which substantially balance each other.

The possibility of resistance to flow at the entrance to, and the exit from, the rotor longitudinal cooling ducts J, shown in Figure 3, was brought to the writer's attention by Mr. C. M. Laffoon and Mr. R. A. Baudry of Westinghouse Electric Corporation. The further study of Coriolis' acceleration which was prompted by Laffoon and Baudry's warning led to a study of various means for mitigating the whirls arising from Coriolis' forces.

Discussion

D. S. Snell and C. E. Kilbourne (General Electric Company, Schenectady, N. Y.): The advantages of liquid cooling for rotating electric machines have long been recognized, and much time and effort have been expended by various manufacturers in the endeavor to make the application of liquid cooling to such machines a practical possibility. From a thermal standpoint, water is the ideal cooling agent for rotating electric machines and Mr. Fechheimer's analysis of the gains in output for turbine generators obtainable through a combination of water and hydrogen cooling in place of direct-hydrogen cooling appears to be entirely sound. In fact the gains he has shown are substantially confirmed by an analysis of stator and rotor heating for hydrogen-cooled generators given in a paper by D. S. Snell on Loading of Hydrogen-Cooled Generators at Elevated Gas Pressures[1] presented recently.

In Figures 6 and 16 of the Snell paper the temperature rises of the stator and rotor windings respectively, of a hydrogen-cooled generator, are shown to be made up of several components, some of which are influenced by the hydrogen pressure, others are independent of it. It can be shown readily that the components of temperature rise which are influenced by the hydrogen pressure would be nearly eliminated by the use of water cooling in place of direct hydrogen cooling; and since these components com-

Figure 1. Horizontal hydrogen-cooled a-c generator with cooling pads in stationary-armature core

Figure 2. Unwound stationary armature for hydrogen-cooled a-c turbine generator rated at 50,000 kva, 3,600 rpm, 11,000 volts, 60 cycles, type ATB, 2 pole

prise, at 1/2-pound hydrogen pressure, approximately one-half of the total temperature rises of the windings, the use of water cooling in place of direct hydrogen cooling would reduce the temperature rise at a given load by nearly one-half; hence a large gain in output for the same temperature rises would be obtained.

It also is shown in the Snell paper,[1] that the temperature rise components which are influenced by hydrogen pressure become very small at high hydrogen pressures, so that at some pressure, possibly 50 pounds per square inch or higher, hydrogen cooling would become, from a thermal standpoint, nearly as efficient as water cooling. However, due to the increased windage losses at elevated hydrogen pressures, the operating efficiency of a generator at very high hydrogen pressures would not be as good as that of the generator proposed by Mr. Fechheimer, in which the stator and rotor cores are cooled with water and the end windings of both stator and rotor are cooled with hydrogen at 1/2 or 15 pounds per square inch pressure.

The General Electric Company has had considerable experience in the construction of rotating machines in which the stator is water cooled, and in most cases the cost of the added complications due to water cooling have more than offset the gains derived through increased cooling efficiency. Figures 1 and 2 of the discussion show the construction of the water-cooled stator for a 50,000-kva 3,600-rpm generator which the General Electric Company built for the Logan, W. Va., plant of the Appalachian Power Company, and which has been in successful operation for the past 13 years. The cooling of the stator core and embedded windings is accomplished by the use of hollow cooling pads sandwiched between the lamination packages, through which treated water is circulated. A heat exchanger outside the generator is provided for cooling the treated water. As shown in Figures 1 and 2, two types of cooling pads are used, one type being provided on one side with fins, the other type being plain. The finned pads are used in the center of the stator and serve to cool the hydrogen which is circulated for cooling the stator end windings and the rotor, as well as the core and embedded windings of the stator. The plain pads are used in the end portions of the core and cool only the core and embedded windings.

Although the performance of this generator has been entirely satisfactory and very little trouble with the cooling system has been experienced, this type of stator construction proved to be considerably more costly than the conventional type, using direct-hydrogen cooling and gas coolers, hence no other generators of this type have since been built.

In 1915 the General Electric Company built for test purposes, a 6,250-kva 1,800-rpm generator having a water cooled rotor, the operation of which was described in a discussion of Mr. Fechheimer's earlier paper.[2] This generator was successful from a thermal standpoint but gave considerable trouble mechanically. Mr. Fechheimer has demonstrated, by means of a model, that the mechanical problems inherent in the construction and operation of a water-cooled rotor can be successfully overcome. Whether the resultant complications in the rotor construction and in the auxiliary equipment will prove objectionable is another question, however, and this will require further study.

In the past several years hydrogen cooling has almost completely superseded air cooling for generators in sizes from 25,000 kw up, and now is being regularly applied to generators as small as 15,000 kw. Whether the additional expense of the hydrogen features can be justified for generators in these small sizes is debatable. Should water cooling be seriously considered as a successor to hydrogen cooling for generators, the lower limit of capacities in which water cooling would be economical would doubtless be considerably greater than with hydrogen cooling. It is quite possible, however, that for generators larger than about 60,000 kw, the additional cost and complication of water cooling would be more than offset by the savings due to the reduction in the amount of active material in the generator effected through water cooling. Also, for generators in sizes appreciably larger than those now being built with hydrogen cooling, it is probable that either a combination of water and hydrogen cooling as proposed by Mr. Fechheimer, or the use of direct-hydrogen cooling at very high pressures, would be necessary in order to make the construction of generators in these sizes a possibility.

We consider that Mr. Fechheimer deserves much credit for the design he has proposed, and for his persistence in promoting a system of generator cooling which offers as much promise as does liquid cooling.

Th. de Koning (Consulting Engineer, Philadelphia, Pa.): It is a pleasure to compliment Mr. Fechheimer on his paper. Why liquid cooling has been neglected for so long was a puzzle to me until I came to the conclusion that hydrogen cooling was so similar to air cooling that at first glance it looks as if the changes needed in the construction, and the development cost, would be small.

As is practically always the case when one takes half-measures, this one backfired. I have been told that hydrogen-cooling development costs were, and still are, outrageously high. This may be the reason why, when one dares suggest a better method of cooling, million dollar development cost-estimates regularly fly through the air. Perhaps Mr. Fechheimer will give us an idea of his development costs up to now?

We will all agree, according to the paper, the rotor design has been considerably improved. However the danger of the water circuits springing a leak, at a welded joint for instance, are not entirely eliminated. Should this happen, the end windings with the new construction of the stator, will get doused by part of the water-content of the rotor circuit. This calls for further improvement. I was glad to hear that the danger of air disturbing the rotor balance is eliminated. Did Mr. Fechheimer make tests of very long duration?

I regret that relatively so little space was given in the paper to liquid cooling of the stator. Liquid-cooled machines are small in size and weight, the stator core does not need air vents, and the insulation is more favorably stressed. A life time with air- and hydrogen-cooled machines must have left its mark. In the new design we get the air vents back in another form. The multitude of intricately bent small diameter water tubes now used is much more vulnerable and cools less evenly than the longitudinal channels in the solid stator core used in Mr. Fechheimer's earlier paper. See Figure 4 of the present paper.

A feature of liquid cooling in general, and of cooling the stator core in special, is that worked-out liquids used in the hydrogen coolers or vapor condensers are suitable. This cuts down on the amount of circulation liquid needed, and if boiler feedwater is used, the losses improve the thermal efficiency of the steam cycle. As the air gap is in the center of the heat losses, I do not consider it sound to attempt to ignore air

gap cooling since it has to be used for the end windings. Let each do its proper share, and with increasing load, the percentage of the stator iron and copper losses to be removed by liquid cooling can be increased very effectively.

My main objection is that when hydrogen is used for the air-gap all the difficulties with explosion proofing, shaft sealing, and hydrogen purity, and their auxiliary equipment remain. This reduces the attractiveness of this method of cooling very much. With air, hydrogen and vaporization cooling, all the heat is gathered by one medium. We cannot remove the hydrogen coolers, as about 3/10th of the rotor and stator copper losses remain to be removed by these coolers.

I think it reflects great credit on Mr. Fechheimer that, though he was instrumental in bringing hydrogen cooling to where it is today, he realizes that a better method of cooling is badly needed.

Carl J. Fechheimer: The commendatory statements of the discussers are very gratifying. I am pleased that Messrs. Snell and Kilbourne agree substantially with the gains given in Table I. In my opinion those rating ratios are conservative, and future experience will probably indicate that the water-cooled machine could be rated even higher.

The highest hydrogen pressure listed in that table is two atmospheres. With the same proportions as in the first seven items, a rotor with water in the ducts and with surroundings of one atmosphere of hydrogen, as compared with 30 pounds per square inch gauge of hydrogen in ducts and surroundings, gives a rating ratio of 1.27. Even if the hydrogen pressure is elevated to 50 pounds per square inch gauge, the rating is appreciably less than for the same water-cooled rotor. As stated by the discussers, the windage with the higher pressures affects the efficiency, and to a minor extent, the temperatures. Mr. Snell showed in his paper on elevated pressures that the rate of rating increase diminishes fairly rapidly as the pressures are raised; it is questionable whether it will pay to operate a hydrogen-cooled generator at pressures appreciably higher than 30 pounds per square inch gauge.

It is regrettable that the generator with a water-cooled stator built by General Electric Company some years ago was expensive. Recognition should be given to the following:

1. The first machine built in which the construction departs from previous machines, is always considerably more costly than succeeding ones with the new construction.

2. That the generator was probably limited by rotor heating; consequently, the stator's reduced temperature could not show advantageously from the cost standpoint. With the proportions obtainable with water cooling for rotor and stator, the over-all dimensions would be reduced and the cost would be lowered greatly.

3. The construction of the cooling pads is such as to make them expensive in comparison with the construction that I propose. Also, I am quite certain that a considerably larger number of pads were used than would be needed to obtain the usual guaranteed temperature. That is easily understandable, as it was the first of its kind. It is gratifying that the generator has been operating satisfactorily for 13 years; that should help to answer those who fear that a weld might leak.

As stated by the discussers, there is little doubt that the smaller and medium-sized generators can be made with considerable savings, with air for the surrounding internal gas. It is my belief that the reduction in D^2L obtainable with water cooling will reduce the costs so much that they can be water-cooled to advantage for sizes much smaller than 15,000 kw. Note that in Table I the 20-inch diameter is for a 10,000-kva rotor.

I am confident that large savings can be effected with generators larger than 60,000 kw also. Thus, the diameters and the length can be considerably reduced. The rotor diameter for 100,000 kva need only be 34 inches for 3,600 rpm, and then the stresses are sufficiently low to admit of standard carbon steel forging. It is my understanding that for an equal rating with hydrogen cooling the rotor diameter is such as to necessitate expensive alloy steel.

I suggest that comparisons be made by the estimating department of one or more manufacturers, of the cost of a large hydrogen-cooled generator, and one of equal rating that is water cooled. I would be pleased to co-operate in every way that I can. I believe that the engineers will then be surprised when they learn how large the savings will be. It is well that Messrs. Snell and Kilbourne consider water cooling favorably for generators for outputs greater than have been built so far.

In Figure 13 in the paper by Mr. Snell on elevated pressures, two ducts are shown for each rotor slot. Their combined sections are considerably greater than for water cooling. (Thus, for 100,000-kva rotor, the water duct dimensions are 0.188×2.4 inches.) Milling of two sets of ducts plus the extra milling for the small wedges for the tooth tunnels increases the cost of manufacture. Mr. de Koning's fears of the possibility of a water circuit springing a leak requires serious consideration. It is important that the duct systems be checked for leaks after completing the welds. In the model, after checking and welding leaks, before any water was admitted, there was no further trouble from that source. High-pressure high-temperature gasoline-cracking stills are welded, and it would be very serious if one of them were to spring a leak. High-pressure high-temperature boilers and piping are welded. The pressures and temperatures are low in the water-cooled stator. For the rotor, the temperatures are low, but the pressure in the cooling ducts may be of the order of 1,500 pounds per square inch in a 100,000-kva rotor. For both stator and rotor conditions are far more favorable than for the cracking-still or boiler. Skilled workmanship is required for the present hydrogen-cooled turbogenerator, and high-grade workmanship is needed for the water-cooled turbogenerator also.

As regards water cooling for the stator, the heat absorption and heat transfer rates with turbulent flow are so favorable that the heat can be transferred readily from the steel laminations to the water in the square tubes, even with the small surfaces. As stated in the paper, an insulating liquid is preferable from the thermal standpoint, particularly for high stator voltages.

The smaller D^2L obtainable with liquid cooling is advantageous to a utility company. For a given rating the ratio of D^2Ls is substantially the reciprocal of the ratio of ratings as given in Table I in the paper. Both the diameters and the length would be reduced, and consequently the weight would be less. This would then lower the cost of the generator's foundation. Also, the shorter length would mean lower building costs. These cost gains are in addition to the lower first cost of the generator itself.

Surface Heat-Transfer Coefficients for Hydrogen-Cooled Rotating Electric Machines

D. S. SNELL
MEMBER AIEE

R. H. NORRIS
NONMEMBER AIEE

MRS. B. O. BUCKLAND
MEMBER AIEE

Synopsis: A method is given for calculating the surface heat-transfer coefficients for hydrogen-cooled rotating electric machinery from the values of these coefficients as determined from tests in air. The influence of hydrogen purity and of the velocity exponent on the ratio of heat transfer in hydrogen to heat transfer in air is evaluated; also, for gas flowing in ducts, the effect of the type of flow on this ratio is discussed. A method is also given for calculating the heat-transfer coefficients for ventilating ducts, in either air or hydrogen, on an inlet temperature basis, as an aid to simplifying the calculation of the surface temperature rise.

IN THE calculation of the heating characteristics of rotating electric machinery, a knowledge of the heat-transfer coefficients which apply for the various cooling surfaces is essential. While values of these coefficients have been fairly well established for air-cooled machinery, relatively little has been published regarding the corresponding coefficients in hydrogen; and the few data which have been published appear to be inconsistent among themselves. (For example, in 1924, C. W. Rice[1] stated "the forced convection for high velocities over plane surfaces will be approximately equal in air and pure hydrogen and approximately 13 per cent greater in commercial hydrogen." In 1936, G. W. Penney[2] showed that for flat ducts a ratio of heat transfer in hydrogen to heat transfer in air of between 1.45- and 1.25-to-1 may be obtained in turbulent gas flow, while for velocities giving laminar flow in hydrogen the ratio may be considerably greater. Other authorities have given the hydrogen-air heat-transfer ratio as between 1.5- and 1.35-to-1.) In this paper an attempt has been made to reconcile these inconsistencies and to arrive at a basis for evaluating the heat-transfer coefficients in hydrogen from the values of these coefficients as determined from tests in air.

In the first section of the paper the various cooling surfaces in an electric rotating machine have been classified from a heat-transfer standpoint; then by the use of a convenient form of correlation which can be used for experimental data for any of these different surfaces, a general equation is derived. This equation gives the ratio of heat transfer in hydrogen to heat transfer in air (hereinafter often called merely the "hydrogen-air ratio") as a function of the ratios of the various gas properties and as a function of the exponent of the velocity in the correlation chosen to represent the heat-transfer coefficient for air.

Next, the available experimental data on heat transfer in hydrogen have been reviewed in an endeavor to confirm the accuracy of the derived equation for the hydrogen-air ratio. Satisfactory confirmation is obtained except for experiments wherein the hydrogen flow was not fully turbulent, so that comparison with fully turbulent air flow was not justified. Attention is thereby directed to the influence of the character of the gas flow on the hydrogen-air ratio for ventilating ducts.

For an ideal duct, having both smooth surface and rounded entrance, the minimum velocity limit for fully turbulent flow is much higher for hydrogen than for air. The hydrogen-air ratio for smooth ducts therefore may be considerably affected by a decrease in velocity below the limit of the turbulent range. The lower part of the range of gas velocities encountered in an idealized ventilating duct of a hydrogen-cooled machine is below this limit and therefore corresponds to flow with little or no turbulence.

For a duct having inlet conditions more closely simulating an actual ventilating duct in an electric machine, however, tests made by one of the authors indicate that the gas flow in such a duct may be fully turbulent, even though calculations indicate that laminar flow would be expected if the duct entrance were rounded; consequently the hydrogen-air ratio for turbulent flow seems likely to be applicable to lower velocities in such ducts than had been expected, and perhaps will apply to all of the ducts encountered in practical design work on rotating electric machines.

An example then is given, showing how the equation for the hydrogen-air ratio may be applied for determining the heat-transfer coefficients in hydrogen for a typical cooling surface in a hydrogen-cooled machine, from values of the coefficients determined from tests in air.

Finally, a method is described by which the heat-transfer coefficients for ventilating ducts, for either air or hydrogen, may be calculated on an inlet-temperature basis; which, for ducts of appreciable length, is frequently more convenient than the average-temperature basis commonly used.

Hydrogen-Air Heat-Transfer Ratio in Turbulent Flow for the Cooling Surfaces in Rotating Electric Machines

The principal cooling surfaces in hydrogen-cooled rotating electric machines from

Paper 50-29, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 23, 1949.

D. S. Snell, R. H. Norris, and Mrs. B. O. Buckland are all with the General Electric Company, Schenectady, N. Y.

which heat is dissipated through forced convection are the following:

1. Radial ventilating ducts between stator laminations.
2. Axial and radial ventilating ducts in rotors (for turbine generators).
3. Outside surface of stator core.
4. Inside bore surface of stator.
5. Outside peripheral surface of rotor.
6. Sides of salient pole.
7. Rotor end windings (for turbine generators).
8. Stator end windings.
9. Finned tubes of surface gas cooler.

In the literature on heat transfer, theoretical and empirical relations have been derived for heat transfer from various types of surfaces by forced convection. These relations have been derived by the use of dimensional analysis for the form of the equations, and by tests to determine various numerical constants appearing in the equations.

Evaluation of the numerical constants depends upon the properties of the gas and hence upon the temperature for which the properties are evaluated. It is therefore essential, in employing any one of the various empirical correlations, to evaluate the gas properties for the temperature on which that particular correlation is based. This basis may be wall temperature, film temperature, inlet temperature, or average of inlet and outlet temperatures; but whichever it is, it should be recognized and used.

Most of the cooling surfaces, listed previously in an electric machine, may be classified as belonging to one or the other of these three types of configuration:

1. Internal surface of a duct, not necessarily round, but of a length which is much larger (by, say, 20 times) than the equivalent diameter. The diameter and not the length is here found to be the significant dimension for evaluating both the heat-transfer coefficient and also the Reynolds Number (the significance of which will be discussed later).

2. External surface of a body exposed to gas flow which is either parallel to the surface, starting at a leading edge, as for a flat plate, or perpendicular to the axis of the surface, as for flow across a cylinder, or across a salient pole, or across the conductors of an end winding. The dimension along the surface, more or less parallel to the flow, is here the significant dimension for evaluation of the heat-transfer coefficient and of Reynolds Number; for a flat plate it is length of the plate; for flow across a cylinder the cylinder diameter is commonly used.

3. Peripheral surface of rotor, and the stator surface immediately adjacent thereto. The clearance distance between rotor and stator here is believed to be the significant dimension.

For such surfaces in forced convection, it is convenient and customary in chemical and mechanical engineering to evaluate the heat-transfer coefficient as a product of several factors, in a form suggested by Colburn,[3] namely

$$h = jcG(c\mu/k)^{-2/3} \qquad (1)$$

This equation gives the value of the heat-transfer coefficient h in terms of mass velocity G, the gas properties c, μ, and k, and the dimensionless heat-transfer factor j. The factor j provides a useful means for correlating heat-transfer data on surfaces of different shapes; numerically, for many common shapes, it is approximately equal (within ±20 per cent) to the half-friction factor $f/2$, where f is the friction factor in the Fanning equation in hydraulics.

Using values of j determined by experiment equation 1 will be utilized in the following to determine the hydrogen-air ratio in turbulent flow for examples of two of the three classifications of surface mentioned previously. Treatment of the third could be made similarly.

A. Inside Surface of Smooth Straight Ducts

For this type of surface, which is the simplest example of ducts in general, the empirical relation for j in terms of Reynolds Number D_eG/μ and of length-to-diameter ratio L/D is plotted* in Figure 1. Only for Reynolds Numbers less than 8,000 does the ratio L/D have a controlling effect on the heat transfer, but then the curves here shown are restricted to round ducts; Norris and Streid[4] give

* The curves in Figure 1 are taken from reference 4 except that the values in the turbulent range have been reduced by 10 per cent to agree better with the consistent trend of more recent test results, including those of reference 5.

Figure 1. Heat transfer factor j for smooth straight round ducts, for gases with Prandtl Number $c\mu/k$ less than 1.5

Points shown obtained from tests by Colburn and Coghlan on tube 0.5 inch in diameter by 49 inches long with calming section 87 inches long, using various hydrogen-nitrogen mixtures. Test points: × = 98 per cent; ⊙ = 98.4 per cent; △ = 86.8 per cent; ⊡ = 55 per cent; ⊗ = 42.9 per cent (hydrogen in nitrogen, by volume)

Figure 2. Ratios of properties of hydrogen-air mixtures to properties of air at 50 degrees centigrade

Figure 3. Calculated hydrogen-air heat-transfer ratio versus hydrogen purity for three types of surface. Also Prandtl Number versus hydrogen purity

Curves: 1—Heat-transfer ratio for gas flowing over staggered banks of cylindrical tubes. Velocity exponent $n=0.6$. 2—Heat-transfer ratio for gas flowing in smooth straight ducts or over plane surfaces. Velocity exponent $n=0.8$. 3—Prandtl Number $c\mu/k$

similar curves for flat ducts. For Reynolds Numbers, R, above 8,000, where the gas flow is fully turbulent, the heat-transfer factor is well known to be independent of L/D (unless the duct is short, with L/D well below 20 or so[4]). Furthermore the shape of the duct cross-section is immaterial (for common shapes, such as rectangular) as long as the equivalent diameter is used. For values of R below 2,100, laminar flow is usually assumed to be present. (The quantity j is defined in terms of the logarithmic mean temperature difference for all data in Figure 1. In the earliest publication of such curves, by Colburn,[3] the heat-transfer coefficient was defined in terms of arithmetic-mean temperature difference in the range of laminar flow. Norris and Streid[4] converted Colburn's curves to a mean logarithmic basis throughout, and Colburn and Coghlan[5] later used this basis for all their test results.)

For values of R between 8,000 and 2,100, the gas flow may be in the transition state between turbulent and laminar flow (the so-called dip region). The velocity corresponding to $R=2{,}100$ is commonly designated as the critical velocity, above which the flow is no longer laminar. The test points plotted in Figure 1 show results of tests made by Colburn and Coghlan[5] on a smooth tube of 0.5-inch inside diameter by 126 inches long, with various mixtures of hydrogen and nitrogen.

To determine the hydrogen-air ratio for gases in turbulent flow in ducts, the single curve in Figure 1 for $R>8{,}000$ will be assumed to apply. It may be expressed by the equation[8]

$$j=0.021\ (D_eG/\mu)^{-0.2} \tag{2}$$

where D_e is the equivalent inside diameter of the tube, G the mass velocity, and μ the viscosity evaluated at an average between inlet and outlet gas temperatures.

Substituting equation 2 in 1 and using $G=V\rho$ gives

$$h=0.021\ cV^{0.8}\rho^{0.8}(D_e/\mu)^{-0.2}(c\mu/k)^{-2/3} \tag{3}$$

as the equation for heat transfer in turbulent flow in smooth straight ducts. Letting h_{m1} represent the heat-transfer coefficient for a hydrogen mixture, and h_{a1} the coefficient for air, both at atmospheric pressure, the hydrogen-air ratio for a given gas velocity and for a given duct, is, from equation 3

$$h_{m1}/h_{a1}=(c_m/c_a)(\mu_m/\mu_a)^{0.2}(\rho_m/\rho_a)^{0.8}\times\left[\frac{(c\mu/k)_a}{(c\mu/k)_m}\right]^{2/3} \tag{4}$$

B. Plane Surfaces

Experiments by Nusselt and Jurges[6] on heat transfer from a large isolated plane surface, with gas flowing parallel to the surface and with a boundary layer which is turbulent, can be correlated by the relation

$$j=0.0346(LG/\mu)^{-0.2} \tag{5}$$

where L is the length of plane in direction of gas flow and G is mass velocity relative to the surface.

Substituting equation 5 in 1 and using $G=V\rho$ gives

$$h=0.0346\ cV^{0.8}\rho^{0.8}(L/\mu)^{-0.2}(c\mu/k)^{-2/3} \tag{6}$$

as the equation for heat transfer for an isolated plane surface, in turbulent flow. Since the exponents of the several terms in equation 6 are the same as those of the corresponding terms in equation 3, it is evident that the hydrogen-air ratio for this type of surface will also be given by equation 4.

Figure 4 (left). Calculated ratio of heat transfer in hydrogen-air and hydrogen-nitrogen mixtures to heat transfer in air versus velocity exponent (equation 11). Test values shown for comparison

V_c = critical velocity, corresponding to $R = 2{,}100$

C. Flow Over Banks of Tubes

Analysis by Colburn of experimental data gives the relation for heat transfer in turbulent** gas flow normal to staggered tube banks, as

$$j = 0.33\ (D_oG/\mu)^{-0.4} \tag{7}$$

where D_o is the outside tube diameter and G is the average mass velocity through the minimum cross section area between tubes. Substituting equation 7 in 1 and using $G = V\rho$ gives

$$h = 0.33c\ V^{0.6}\rho^{0.6}(D_o/\mu)^{-0.4}(c\mu/k)^{-2/3} \tag{8}$$

as the equation for heat transfer for staggered tube banks in turbulent flow. For this type of surface the hydrogen-air ratio, from equation 8, is

$$h_{m1}/h_{a1} = (c_m/c_a)(\mu_m/\mu_a)^{0.4}(\rho_m/\rho_a)^{0.6}\times\left[\frac{(c\mu/k)_a}{(c\mu/k)_m}\right]^{2/3} \tag{9}$$

Inspection of equations 3, 6, and 8 shows that for the three types of surface here considered, a general equation for the heat-transfer coefficient for turbulent flow may be written, of the form

$$h = C_1c(\mu/L')^{1-n}V^n\rho^n(c\mu/k)^{-2/3} \tag{10}$$

where C_1 is a constant, L' the characteristic dimension of the surface, and n is the velocity exponent. (For cases A and B, $n = 0.8$; for case C, $n = 0.6$. For case A, $L' = D_o$; for case B, $L' = L$; for case C, $L' = D_o$) It can also be shown that equation 10 will apply to certain common types of laminar flow, but with different values for the constants C_1 and n.

Finally, from equation 10 a general equation for the hydrogen-air ratio for a given surface and a given gas velocity may be written in the form

$$h_{m1}/h_{a1} = (c_m/c_a)(\mu_m/\mu_a)^{1-n}(\rho_m/\rho_a)^n\times\left[\frac{(c\mu/k)_a}{(c\mu/k)_m}\right]^{2/3} \tag{11}$$

where n will be specified by the type of surface and flow involved, but must be the same for the hydrogen mixture as for the air, as pointed out later, if equation 11 is to be valid.

Influence of Gas Impurities and of Velocity Exponent

The general equation 11 for the hydrogen-air ratio in turbulent flow derived in the foregoing section shows this ratio to be determined by the ratios of the gas properties and by the velocity exponent in the heat-transfer equation; the latter, in turn, being determined by the type of surface.

To illustrate the influence of hydrogen impurities on the hydrogen-air ratio, the latter will be calculated for values of $n = 0.8$, corresponding to surfaces of cases A and B; and 0.6, corresponding to case C, in the foregoing section. Assuming an average gas temperature of 50 degrees centigrade, the ratios of the various gas properties given by equation 11 have been calculated for different percentages of hydrogen in air, by volume, as shown in Figure 2. It will be observed that $c_m/c_a = \rho_{a1}/\rho m_1$ for the hydrogen mixtures considered. It also is noted that the ratio $(c\mu/k)_a/(c\mu/k)_m$ shows a marked variation with hydrogen purity, even though the values of $c\mu/k$ for air and pure hydrogen are the same. This follows from the fact that the ratios c_m/c_a, μ_m/μ_a, and h_m/h_a vary in different manner with changes in hydrogen purity, as explained in reference 7.

by Figure 2 have been applied in equation 11 to calculate the hydrogen-air ratio for the various types of surfaces at different values of hydrogen purity, as shown in Figure 3. It will be observed that for gas flow in smooth ducts or over plane surfaces, where $n = 0.8$, the hydrogen-air ratio has a value for pure hydrogen of 1.47; with decreasing purity the ratio at first increases, reaching a value of 1.68 for 82 per cent hydrogen in air, and then decreases. (For pure hydrogen the above value of the ratio is the same as was found by Pohl[8] for heat transfer in smooth tubes, by the use of the Nusselt equation for heat transfer, in which $n = 0.786$.) For gas flow over staggered tube banks, where $n = 0.6$, Figure 3 indicates that the ratio is 2.16 for pure hydrogen and rises to a maximum of 2.21 for a 94 per cent hydrogen-air mixture.

To show the effect of the velocity exponent n on the heat-transfer ratio, the latter has been calculated from equation 11 for several values of n from 0.6 to 1.0, and for four different values of hydrogen purity, using both air and nitrogen as the contaminating gas, with the results shown in Figure 4. The ratio is shown to increase sharply with decreasing n, while the influence of hydrogen purity on the ratio is shown to be the greatest for the highest values of n, and vice versa. For $n = 1.0$, which corresponds approximately to the type of flow in rough-walled ducts (as in axial ducts through iron laminations), the ratio is less than unity for pure hydrogen, but is 1.32 for 85 per cent hydrogen purity.

Correlation of Published Data on Heat Transfer in Hydrogen

Figures 5 and 6 give heat-transfer coefficients in hydrogen and air for several types of surfaces as determined from tests by various investigators. Many of the data in hydrogen were obtained at velocities sufficiently low for the turbulence of the flow to be open to doubt, however, whereas the corresponding tests for air indicated fully developed turbulent flow; so that the resulting hydrogen-air ratio may be considerably different than the ratio appropriate when the flow is turbulent for both gases. (This is a consequence of the fact, pointed out by Penney,[3] that the kinematic viscocity (μ/ρ) of hydrogen is seven times that of air; hence the fact that the Reynolds Number is in the turbulent range for air does not imply that it remains in this range for hydrogen, at the same velocity.) Since, however, a check is desired for the accuracy of the hydrogen-air ratio given by equation 11 and Figure 4, which presuppose the same velocity exponent for both air and hydrogen, only the data corresponding to fully developed turbulence in both gases will here be considered significant for this use.

Figure 5(A) presents some data from the earliest published tests on heat transfer in hydrogen, but these data are not here considered significant, for the reasons just given. The tests were made by Rice[9] on a torpedo-shaped heater, 1.1 inches in diameter by 5.9 inches long, enclosed in a cylindrical duct 2 inches in inside diameter, the gas flowing axially in the annular space surrounding the heater. It is evident that the slope of the curve for the hydrogen-nitrogen mixture is lower than that for air. Furthermore, the general magnitude of all the data in Figure 5(A) are much above the magnitude to be ex-

Figure 8 (left). Monel-metal stator cooling pad for turbine generator

Figure 9 (right). Half cooling pad assembled in test box, with cover removed

pected from all subsequent tests on similar configurations; unfortunately the reason for this latter discrepancy is not evident.

Figure 5(B) presents results of tests by Penney[5] on a flat duct, for both air and pure hydrogen. Here again the slope of the test curve for hydrogen is much less than the slope for air; in fact, all the hydrogen test points but one are below the critical Reynolds Number of 2,100, hence the tests are well below the usual turbulent range. Furthermore, the duct was short enough so that entrance effects were not negligible; the results are therefore not applicable as a check on equation 11 and Figure 4.

Figure 5(C) gives values of the heat-transfer coefficient for a finned-tube heat exchanger as determined by Brunot[7] from tests in air, pure hydrogen, and a 91.8 per cent hydrogen-nitrogen mixture. The degree of turbulence was apparently the same for the air tests and the tests in the other gases, since the slopes of the curves are alike, yielding a velocity exponent of 0.69 and heat-transfer ratios of 1.75 for pure hydrogen and 1.8 for the hydrogen-nitrogen mixture. Referring to Figure 4, these two ratios are observed to be only 4 and 6 per cent respectively below the calculated values of the ratio for $n=0.69$, which may be considered a reasonably good check.

Figure 6 gives the results of several tests made by Colburn and Coghlan[8] for determining the heat-transfer coefficients in a smooth straight tube 0.5 inch in diameter by 49 inches long, with an 87-inch long calming section upstream, using air, nitrogen, and various hydrogen-nitrogen mixtures. These same results have also been included in Figure 1, in the alternative form of j-factor versus Reynolds Number. Values calculated from equation 3 are also shown in Figure 6 and are observed to agree closely with the test values whenever the velocity is well above the critical; furthermore, the velocity exponent, for turbulent flow, was 0.8 for all tests where the velocity was well above the critical.

In Figure 7 the hydrogen-air ratio in turbulent flow, as determined from the values of the heat-transfer coefficients given in Figure 6, is shown for different percentage values of hydrogen in nitrogen, for comparison with the values of this ratio calculated from equation 4. Close agreement of test and calculated values of the ratio is obtained for all values of hydrogen purity covered by these data. Test data are not shown in Figure 7 for hydrogen purities above 55 per cent, since all of the test results for such purities were for Reynolds Numbers below 6,000; hence, the turbulence may be questioned.

Tests of a Simulated Stator Ventilating Duct Using Hydrogen

In 1936, in connection with the design of a hydrogen-cooled generator provided with a system of water cooling for the stator core,[10] tests were made by one of the authors, on one of the finned cooling pads which were used in the stator, which furnished information on the relative heat-transfer coefficients and friction factors in hydrogen and air in long, narrow ducts. These tests are described in Appendix II. In the following, the principal results of these tests are given.

Figure 10. Schematic arrangement of test apparatus

Heat-Transfer Tests

The construction of the cooling pads for the water-cooled stator is illustrated in Figure 8. For the tests, one of the finned pads was cut in two between the

padteeth, the opening thus made was brazed shut and a water connection added. The half-pad was assembled in a flat wooden box, with openings at either end for the circulation of gas through the ducts formed by the fins on the outer surface of one side of the pad, Figure 9. Water was circulated through the inside of the pad. The test arrangement is illustrated in Figure 10. The ducts formed by the pad fins were of various lengths and widths; however, about 75 per cent of the total pad and fin surface area was covered by ducts which were of fairly uniform length and cross section. By consideration of the cross section and surface areas of the various ducts it was possible to estimate from the test data the amount of heat absorbed by the center ducts, and thus obtain comparison of the test results with calculated values of heat transfer from conventional ducts.

Figure 11 gives the heat-transfer coefficients for the center pad ducts, as evaluated from the test data, with values calculated from equation 3 for three different values of hydrogen purity shown for comparison. The test points in air are observed to lie on the calculated curve, while most of the points for hydrogen at various purities coincide with the calculated curve for pure hydrogen. One test point for 95 per cent purity checks the calculated curve at this purity; however, a test point for 92.3 per cent purity lies on the calculated curve for pure hydrogen. The test data cannot therefore be considered sufficiently accurate to permit evaluation of the effect of these small variations in hydrogen purity on the heat transfer. The slope of the test curves for both air and hydrogen indicate a velocity exponent of 0.8 and a hydrogen-air ratio of 1.47, checking the value given by the curve in Figure 4 for pure hydrogen for $n=0.8$.

In order to consider how near to the laminar range these test data extend, the data have been expressed in the form of the heat-transfer factor j and plotted versus Reynolds Number as shown in Figure 12.

The j—R curve from Figure 1 for the L/D value pertinent to the center pad ducts also is shown. It will be observed that, except for two test points which lie below the trend of all the rest, all of the test points, for both hydrogen and air, agree closely with the curve calculated from equation 2 even for values of R well below the critical. This indicates that completely developed turbulence was present in the ducts down to Reynolds Numbers much lower than would be expected from experience with ducts with calming sections or rounded inlets.

Friction-Loss Tests

Following the heat-transfer tests, tests were made to determine the pressure loss in the pad at various gas velocities in both air and hydrogen. From the measured total pressure drop across the pad assembly, the friction loss in the pad ducts was estimated by deducting the calculated losses in the pad enclosure plus an estimated duct entrance loss calculated for two different assumed values for the entrance-loss coefficient, K_e, namely: 0.3 and 0.5. From the friction losses thus determined, the half-friction factor was calculated from the equations given in Ap-

Figure 13. Half-friction factor $f/2$ from stator cooling pad tests in air and hydrogen-nitrogen mixtures

Values shown are calculated by deducting from measured total losses the calculated external losses and the duct entrance losses as estimated for loss coefficient K_e assumed = 0.3 and 0.5. pendix II, the calculated values being shown in Figure 13 for the different values of Reynolds Number. Figure 13 also gives the theoretical values of $f/2$ as presented by Colburn.[3]

It will be observed that the values of $f/2$ calculated from the pad tests for the assumption of $K_e = 0.5$ agree reasonably well with the theoretical values for fully developed turbulence, and that all values lie on a smooth curve which extends far into the transition and laminar regions of flow.

Since the half-friction factor should bear a nearly constant relation to the heat-transfer factor j, the similarity of the test curves of j and $f/2$ as shown in Figures 12 and 13 respectively tends to support the conclusions obtained from the heat-transfer tests.

It may be concluded from both the heat-transfer and friction-loss tests, therefore, that entrance conditions in the pad enclosure were such as to induce turbulent gas flow in the ducts even for hydrogen velocities considerably below the values customarily regarded as critical. The length/diameter ratio for the pad ducts was many times greater than is ordinarily used in the ventilating ducts of an electric machine, so that the duct entrance conditions in the latter case should be even more certain to promote turbulence than was the case in the pad tests.

It therefore seems likely that turbulent gas flow will be obtained in the ventilating ducts of hydrogen-cooled machines at velocities below which nonturbulent flow could theoretically be obtained. It also was shown that the hydrogen-air ratio obtained in the tests, at hydrogen purities between 92 and 99.8 per cent, checked the values of this ratio for pure hydrogen given by Figure 4.

Heat-Transfer Coefficients as Evaluated for One Type of Hydrogen-Cooled Surface, Including the Effect of the Hydrogen Pressure

It has been shown in the foregoing sections of the paper that the calculated ratios of heat transfer in hydrogen to heat transfer in air, as given by equation 11 and Figure 4, are in general agreement with available test data except where the turbulence is less in the hydrogen tests than in the air tests. It is evident, furthermore, from Figure 4, that the effect of impurities in the hydrogen, for hydrogen purities above about 95 per cent, is relatively small for the common range of n-values from 0.6 to 1.0. Considering that the gas purity in hydrogen-cooled machines is usually maintained as high as practicable (between 95 and 99 per cent),

Figure 16. Values of the modulus ϕ in equation $h' = cG\phi$, for surface heat-transfer coefficient on an inlet temperature basis, for smooth straight ducts with different ratios of length to equivalent diameter

it is often sufficiently accurate (and also conservative) to assume that the hydrogen-air ratio given by Figure 4 for pure hydrogen can be used without regard to the degree of impurity when considering the various cooling surfaces in hydrogen-cooled machines. The heat-transfer coefficients in hydrogen at atmospheric pressure therefore may be obtained from the coefficients determined for these surfaces in air, merely by multiplying the latter by the value of $h_{m1}/_{a1}$, for pure hydrogen from Figure 4 corresponding to the velocity exponent n determined from the air tests.

Since the pressure of the hydrogen is, however, always above atmospheric in practice, an additional factor must be used to show the effect of pressure on the heat transfer. From equation 10, which shows the heat transfer to be proportional to the nth power of the gas density, the heat transfer for a given gas velocity at a given temperature must be proportional to p^n, where p is the hydrogen pressure in atmospheres. The gas properties other than density in equation 10 have been shown by Nusselt to be independent of pressure, for pressures at least up to 190 pounds per square inch gauge. Hence for a given gas velocity and temperature, the heat-transfer coefficient in hydrogen at any pressure is

$$(h_m)_p = (h_{m1}/h_{a1})p^n h_{a1} \qquad (12)$$

To illustrate the use of equation 12 in calculating the heat-transfer coefficients in hydrogen for rotating electric machines, these coefficients will be calculated for axial ventilating ducts in the rotor of a turbine generator, having an equivalent diameter of 0.75 inch. Since such ducts are relatively smooth, and are sufficiently long so that entrance effects are unimportant, the heat-transfer coefficient may be assumed to be given by equation 3, in which $n = 0.8$. Figure 14 gives the heat-transfer coefficients in air as calculated from this equation for an average gas temperature in the duct of 50 degrees centigrade, and for gas velocities calculated for an inlet temperature of 40 degrees centigrade. To correct the coefficients for any other temperature t_C, the coefficients should be multiplied by the correction factor

$$K_{t40} = \left[\frac{273+40}{273+t_C}\right]^n$$

since density, for a given pressure, is proportional to the reciprocal of absolute temperature, $(t_C + 273)$.

Referring to Figure 4, the hydrogen-air ratio for pure hydrogen at $n = 0.8$ is 1.47. The equation for heat transfer in hydrogen for this type of surface, from equation 12, is therefore

$$(h_m)_p = 1.47p^{0.8}h_{a1}$$

where h_{a1} is given by the curve of heat transfer in air in Figure 14. Substituting values of h_{a1} from this curve in the above equation, together with different values of p, gives the curves of heat transfer in hydrogen at various pressures shown in Figure 14.

These curves are valid, however, only on the assumption of turbulent flow, which may be assumed without question only for values of R above about 8,000; hence for lower values of R turbulence will depend upon the duct entrance conditions. In Figure 15 curves of R versus velocity for gas flow in ducts of various equivalent diameters, at atmospheric pressure, are given. These curves are useful for determining whether the flow in a duct may be turbulent. To obtain from these curves the value of velocity corresponding to $R = 8{,}000$ at a hydrogen pressure p, the velocity for $8{,}000/p$ should be read. For hydrogen at 0.5 pound per square inch gauge flowing in a duct of 0.75-inch equivalent diameter, reference to Figure 15 for $R = 8{,}000/1.03 = 7{,}750$ indicates a velocity of 10,200 feet per minute. For the critical value of $R = 2{,}100$, the corresponding velocity is 2,700 feet per minute. For hydrogen at pressures of 15 and 25 pounds per square inch gauge, respectively, the duct ve-

Figure 17. Surface heat-transfer coefficients for axial ventilating ducts of turbine-generator rotor in air at atmospheric pressure and in hydrogen at 0.5 pound per square inch gauge pressure, calculated with reference to inlet gas temperature. Average gas temperature 50 degrees centigrade

Curves: 1—Air, $D_e = 0.75$ inch; $L/D_e = 40$. 2—Air, $D_e = 0.75$ inch; $L/D_e = 80$. 3—Hydrogen, $D_e = 0.75$ inch; $L/D_e = 40$. 4—Hydrogen, $D_e = 0.75$ inch; $L/D_e = 80$. 5—Hydrogen, $D_e = 1.0$ inch; $L/D_e = 40$

locities for $R=8{,}000$ are determined from Figure 15 to be 5,200 and 3,800 feet per minute respectively. In Figure 14 the range of velocities corresponding to a range of R-values from 2,100 to 8,000 have been indicated by the dashed portions of the curves.

Considering that the entrance conditions for the axial ducts of a turbine-generator rotor, for which the curves of heat transfer in Figure 14 were derived, are such as to promote turbulence in the gas stream in the duct, and that the tests on a simulated stator ventilating duct described in the preceding section showed that turbulence was obtained in the duct in hydrogen at Reynolds Numbers as low as 1,100, it may be assumed that the curves in Figure 14 are valid for all values of velocity for which the curves are drawn.

The foregoing example illustrates the method of obtaining values of the heat-transfer coefficients in hydrogen from data obtained from tests in air, for one of the cooling surfaces in an electric machine. For other cooling surfaces, similar curves for heat transfer in hydrogen may be derived, providing: 1. that the coefficients for these surfaces in air are known; 2. that these coefficients, when plotted versus velocity on log-log scales, give a straight line; and 3. that the lowest Reynolds Number for the hydrogen curve is not lower than the lowest Reynolds Number obtained in the air test, unless there is reason to expect that the air curve, on log-log scales, if extended, still would give a straight line. The slope of such a line represents the velocity exponent n. Reference to the curve for pure hydrogen in Figure 4 gives the corresponding value of h_{m1}/h_{a1}, which then is substituted in equation 12, giving the equation from which the heat-transfer coefficients in hydrogen at various pressures may be determined.

If condition 2 given in the preceding paragraph should not be met, it still would be possible to obtain curves of heat transfer in hydrogen by plotting the j-factor versus Reynolds Number from the air test. This curve should be the same in hydrogen as in air.

Calculation of Heat-Transfer Coefficients for Ventilating Ducts on an Inlet Temperature Basis

In calculating the temperature rise of the surfaces of ventilating ducts having appreciable length (such as the axial ventilating ducts in a turbine-generator rotor) it is often convenient to use heat-transfer coefficients based on the temperature rise of the surface above the temperature of the gas entering the duct, rather than above the average gas temperature in the duct, which is the usual basis. In Appendix II an equation has been derived for calculating the heat-transfer coefficients for ventilating ducts on this basis, for both air and pure hydrogen. This equation is

$$h' = cG\phi \tag{13}$$

where h' = surface heat transfer coefficient on an inlet temperature basis and

$$\phi = (1-e^{-m})D_e/4L \tag{14}$$

where

$$m = 5.08C_1\frac{L}{D_e}R^{n-1} \tag{15}$$

where C_1 is a constant, to be determined from tests in air.

To illustrate the use of equation 13 in calculating the heat transfer coefficients for a ventilating duct on an inlet temperature basis, the type of duct used in the example in the preceding section will be considered, namely the axial ventilating ducts in a turbine-generator rotor. For this type of surface, $n = 0.8$ and the value of C_1 is 0.021, from equation 3. The value of m, from equation 15, is therefore

$$m = 0.107\frac{L}{D_e}R^{-0.2} \tag{16}$$

Using values of m from equation 16, values of ϕ have been calculated from equation 14 for different values of R and of the ratio L/D_e, and are shown in curve form in Figure 16. These curves permit a convenient evaluation of the factor ϕ at different gas velocities, for ducts of various lengths and equivalent diameters, of the type for which $n = 0.8$.

Assuming an average gas temperature in the duct of 50 degrees centigrade, and an inlet gas temperature of 40 degrees centigrade, and using $G = V\rho$, equation 13 becomes, for either air or pure hydrogen

$$h' = 0.0036\,\rho V\phi$$

Using this equation, curves of heat-transfer coefficients on an inlet temperature basis, versus duct velocity, have been calculated, and are shown in Figure 17, for straight smooth ducts of 0.75- and 1.0-inch equivalent diameter, respectively, for L/D_e = 40 and 80, respectively, and for air at atmospheric pressure and hydrogen at 0.5 pound per square inch gauge pressure. It will be observed that these curves give significantly lower values of heat transfer than the curves for the same type of duct calculated on an average gas temperature basis shown in Figure 14. Also, the effect of duct length on the coefficient calculated on an inlet temperature basis is seen to be appreciable, while the duct diameter is shown to have little effect on the heat transfer.

Summary

The various points developed in this paper already have been summarized in the introduction so will not be repeated here. The main feature of the paper is the determination of the ratio of heat transfer in hydrogen to heat transfer in air, at the same velocity, for different types of cooling surfaces. The results are principally given by equations 11 and 12, and by Figure 4, which illustrate the effect of hydrogen purity, pressure, and velocity exponent on the heat transfer.

Appendix I. Definition of Symbols

A = cross section area
c = specific heat at constant pressure
D = diameter, actual
D_e = diameter, equivalent = $4A/s$
f = friction factor = $(gD_e\Delta p)/(2\rho V^2L)$
g = acceleration of gravity
G = mass velocity = ρV
h = surface heat-transfer coefficient on basis of logarithm of the mean temperature difference between gas and surface
h' = surface heat-transfer coefficient on basis of inlet temperature difference between gas and surface
j = heat-transfer factor, defined by equation 1
k = thermal conductivity
L = length
m = a parameter defined in Appendix III, equation 25
n = exponent of velocity in heat-transfer equation
p = gas pressure, atmospheres
R = Reynolds Number
s = perimeter of duct cross section
t_c = temperature, degrees centigrade
V = velocity
V_c = critical velocity, corresponding to $R=2{,}100$
ρ = density
μ = viscosity
$c\mu/k$ = Prandtl Number

Subscripts

a = air
m = mixture of hydrogen and any impurity (air or nitrogen)
1 = value at a pressure of 1.0 atmosphere

Unless otherwise stated, the above quantities are expressed in the pound, hour, foot, Btu, degree Fahrenheit system. To convert heat-transfer coefficient given in Btu/hour (square feet) (degrees Fahrenheit) to watts/(square inches) (degrees centigrade), divide the former by 273.

Appendix II. Tests on Stator Cooling Pad

Test Arrangement

The cooling pad, on which the heat-transfer and friction-loss tests were made, was designed for the cooling system of a generator stator, and was made from two thin plates of Monel metal having the shape of a single segment of stator laminations, including two teeth. These plates were brazed together at the edges to form a hollow pad through which cooling water could be circulated, see Figure 8. Space blocks within the pad provided the strength to withstand compression and formed passages for the flow of the cooling water. Fins, 0.063 inch by 0.25 inch, brazed to one side of the pad, provided passages between the pad and the adjacent stator lamination for the flow of hydrogen. This same hydrogen also was used for cooling the stator end-windings and the rotor.

The half-pad used in the tests was encased in a flat wooden box, as shown in Figure 9. Gas-tightness was obtained by sealing the joints in the assembly with melted paraffin. A steel lamination 0.025-inch thick was attached by clamps to the underside of the box cover to make contact with the edges of the pad fins. This contact, although not brazed, was nevertheless under enough pressure to allow considerable heat flow from lamination to fins. Between the lamination and the cover an electric heating element was provided, through which the lamination was maintained much closer to the gas temperature than the pad so that the lamination absorbed from the gas only 15 to 20 per cent of the total heat given up by the gas. Temperatures of the pad and lamination were measured by thermocouples located at various points on their surfaces. Gas temperatures at inlet and outlet to the pad ducts were measured by several thermocouples located in the gas stream.

The test arrangement is shown in Figure 10. Two blowers arranged in series, which were housed in a section of 16-inch pipe, circulated the gas through the pad assembly. An electric heater enclosed in a section of 6-inch pipe supplied the heat input to the gas, while water circulating through the cooling pad removed the heat absorbed. A flow nozzle on the discharge side of the pad measured the gas flow. In the hydrogen tests a pressure of about three inches of water was maintained in the system with a gasometer. In the air tests the pipe enclosing the blowers was vented to atmosphere. Before filling the system with hydrogen, the air first was removed with nitrogen; hence this gas was assumed to be the contaminant in the hydrogen in the tests. The hydrogen purity was measured continuously with an Englehard Gas Analyzer, and checked periodically by chemical analysis.

Determination of Heat-Transfer Coefficients From Tests

From the measured total gas flows and the section areas of the various ducts in the pad, the average gas velocities in the various sections of the pad were calculated; the velocities were then corrected to 50 degrees centigrade by multiplying by $323/(273+t_d)$, where t_d is the average temperature in the ducts, degrees centigrade. In estimating the division of heat obtained between pad and lamination, the same heat-transfer coefficients were assumed to apply to both; however, since the pad temperature was very uniform, while that of the lamination showed several degrees variation between different points, the logarithmic mean temperature difference was used between gas and pad, $(\Delta T_m)_p$, and the arithmetic mean temperature difference between gas and lamination $(\Delta T_a)_l$. The combined surface area of pad and fins (assuming fins 100 per cent effective) was 204 square inches, and the area of lamination 84 square inches. Letting q_p and q_l represent the losses to pad and lamination respectively, we can write

$$E=q_p/q_l=\frac{204}{84}\frac{(\Delta T_m)_p}{(\Delta T_a)_l}=2.42\frac{(\Delta T_m)_p}{(\Delta T_a)_l} \quad (17)$$

and for a total loss of q_o watts given up by the gas in passing through the pad ducts

$$q_l=q_o/(1+E) \quad \text{and} \quad q_p=Eq_o/(1+E) \quad (18)$$

From the total losses given up by the gas in the tests, the losses absorbed by the pad and fins were calculated from the above equations, and the average heat-transfer coefficient for the entire pad determined. From this, together with the surface areas of the different sections of the pad and the velocities estimated for the different sections, it was estimated that 75 per cent of the total losses absorbed by the pad and fins was from the center ducts, which were of fairly uniform cross section. (The divergence of fins was under 1 degree.) Using this relation, the heat-transfer coefficients for the center pad ducts were calculated, as shown in Figure 11.

Friction-Loss Tests

From the friction losses in the center ducts of the cooling pad estimated from the test data, as outlined in the text, the half-friction factor $f/2$ was calculated from the equation

$$f/2=\frac{\Delta p_o g D_e}{G^2\,4L} \quad (19)$$

where p = friction loss in ducts, g = acceleration of gravity, D_e = equivalent duct diameter, L = duct length, and the other terms are as defined in the nomenclature. Letting $L=1.56$ and $D_e=0.0235$ for the center ducts, and expressing the pressure drop in inches of water, equation 19 becomes

$$f/2=0.63\,\Delta p''/G^2 \quad (20)$$

where $\Delta p''$ is the estimated friction pressure drop in inches of water.

The values of $f/2$ as calculated from the test data using equation 20 are shown in Figure 13 for comparison with the theoretical values for straight smooth ducts. The latter values were calculated from the equations given by Colburn[3]

$$f/2=14.2/R \quad (21)$$

for the region of laminar flow, and

$$f/2=0.007+0.0625R^{-0.25} \quad (22)$$

for the region of turbulent flow.

Appendix III. Calculation of Heat-Transfer Coefficients for Ducts on an Inlet Temperature Basis

In reference 11 a method is developed for calculating the average heat-transfer coefficient in a ventilating duct referred to the temperature of the gas entering the duct. In the following discussion this method will be utilized in conjunction with equation 10 of the first section of the paper, to determine the heat transfer coefficients for ventilating ducts on an inlet temperature basis, for either air or hydrogen.

Assuming the duct wall to have a constant temperature throughout its length, the heat-balance equation for the mean gas temperature in the duct at a distance x from the entrance is

$$hsdx(t_w-t)=c_pVAdt \quad (23)$$

where t = mean gas temperature at point x; t_w = wall temperature; and the other symbols are defined in Appendix I.

Equation 23 may be written

$$d(t_w-t)/dx=-m(t_w-t)/L \quad (24)$$

where

$$m=sLh/Ac_pV \quad (25)$$

L being the duct length in direction of flow.

Integrating equation 24 gives

$$t_w-t=Ce^{-mx}/L \quad (26)$$

Letting t_o = gas temperature at duct entrance $x=0$, C is determined from equation 26

$$C=t_w-t_o$$

and letting t_L = gas temperature at duct exit, $x=L$

$$t_w-t_L=(t_w-t_o)e^{-m} \quad (27)$$

whence

$$\frac{t_L-t_o}{t_w-t_o}=1-e^{-m} \quad (28)$$

Letting h' represent the average heat-transfer coefficient for the entire duct with respect to the temperature of the gas entering the duct, and q the total loss dissipated to the gas, we may write

$$h'=q/sL(t_w-t_o) \quad (29)$$

To evaluate m of equation 25, use equation 10 for heat transfer in ducts on an average temperature basis, wherein the characteristic dimension is the duct diameter

$$h=C_1cV^n\rho^n(D_e/\mu)^{n-1}(c\mu/k)^{-2/3} \quad (10)$$

and

$$s/A=4/D_e.$$

Then

$$m=4C_1\frac{L}{D_e}R^{n-1}(c\mu/k)^{-2/3} \quad (30)$$

in which C_1 is a constant, to be determined from tests in air.

Assuming an average gas temperature in the duct of 50 degrees centigrade, for which $c_p/k = 0.7$ for either air or pure hydrogen, the expression for m for either of these gases is, from equation 30

$$m = 5.08 C_1 R^{n-1}(L/D_e) \tag{31}$$

which appears as equation 15 in the main text.

Substituting $q = c_p V A(t_L - t_0)$ and equation 28 in 29 gives

$$h' = c_p V A(1 - e^{-m})/sL \tag{32}$$

Using $A/s = D_e/4$ in equation 32 gives equation 13 of the main text

$$h' = c_p V \phi = cG\phi \tag{33}$$

where

$$\phi = (1 - e^{-m}) D_e/4L \tag{34}$$

as the equation for the surface heat-transfer coefficient on an inlet temperature basis.

Discussion

Carl J. Fechheimer (Milwaukee, Wis.): Heat transfer with turbulent flow is associated with the higher values of Reynolds numbers. Then the velocity is usually taken as the volume per unit of time divided by the cross-sectional area. In electric machines, that comparatively simple picture is frequently not applicable. Thus, an obstruction in the fluid's path produces disturbances having characteristics which are entirely different from the simple symmetrical systems of vortices that obtain when the velocity in a smooth duct is raised above the critical value. For example, in the stator radial vent ducts, the gas must pass the coil portions in the vent ducts, which cause severe upsets comparable to disturbances in the Niagara Rapids.

These disturbances generally increase the heat transfer rate and also the pressure drop. Some moving pictures showed the character of flow in the wake of an obstruction to be periodic, changing from one instant to the next, the phenomenon being repeated in regular cycles.

Evidently, with such disturbances, the heat transfer rate changes from one position to the next; it is not a constant, but is a function of location. The total heat transferred (during the steady state), from a surface S is then

$$\int_S h_s \theta ds$$

where h_s is the variable heat transfer coefficient, θ is the difference in temperature between ds and the adjacent fluid, and the integral is taken over the entire surface S.

Might not the turbulent state which was obtained by the authors with hydrogen in a stator with Reynolds number as low as 1,100 be explained by disturbances in the fluid path?

It will be interesting for the authors to tell us under what conditions it is necessary for the Reynolds number to be as high as 8,000 for the flow to become turbulent. It has been my understanding that with smooth straight ducts the transition takes place with Reynolds numbers between 2,000 and 3,500.

The paper is a valuable contribution, but it is well to recognize that there are complexities for which solutions have not yet been obtained.

Sterling Beckwith (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): This paper gives a very useful analysis of heat-transfer rates for hydrogen and air mixtures. One of its main features, and one on which I should like to commend the authors, is the very fundamental and thorough nature of the analysis.

In the course of our studies on hydrogen-cooled machines we have also made tests which check very well the results given for friction factor and for heat transfer. Our tests included much longer ducts (length/width = 300), however, thus reducing end effects, and gave results slightly above those shown for $K_s = 0.3$ in the authors' Figure 13.

I would like to suggest one additional curve which may give a better physical picture of the proportions of a surface heat transfer circuit. This is to plot gas temperature vertically and duct length over duct width horizontally. Then for a parallel-sided duct with fixed wall temperature, the gas temperature will rise exponentially towards the wall temperature and the time constant of the exponential curve will be proportional to the per unit heat transfer coefficient j. For the complete range of the

Figure 1. Gas temperature rise along duct

hydrogen test-data points shown in Figure 11, the suggested curves would be shown in Figure 1 of this discussion. This range of velocities, incidentally, covers reasonably well the normal velocities in the significant portions of almost all hydrogen-cooled generator vent ducts between laminations. For 3/8-inch ducts the "time constant" length is 31 to 36 inches, and for 1/4-inch ducts the "time constant" length is 20 to 24 inches.

D. S. Snell, R. H. Norris, and Mrs. B. O. Buckland: Professor Fechheimer's conclusion about the occurrence of turbulent flow in stator cooling ducts with Reynolds numbers as low as 1,100 being due to disturbances in the fluid path is undoubtedly true. The value of a long calming section or a rounded entrance in securing a conventional laminar-type velocity profile at low Reynolds numbers also is of significance. The upper limit of 8,000 for Reynolds number for transition to turbulent flow comes directly from Colburn and Coghlan's work on hydrogen-nitrogen mixtures, see reference 6 of the paper. In reference to the method of evaluating the total heat transfer coefficient, the test coefficients reported give an integrated average over the whole surface, and no attempt was made to evaluate local heat transfer coefficients.

Mr. Beckwith's confirmation of test results on friction factor and heat transfer is welcomed by the authors, since available data are all too scarce. His method for creating a better physical picture by showing the relation between ultimate hydrogen temperature rise and the length-to-diameter ratio gives a useful concept. For clarity his "time constant" might be defined as the length-to-diameter ratio at which the temperature rise of the hydrogen above inlet gas reaches 63.2 per cent of the rise it would attain in a duct of infinite length and uniform surface temperature. Designation of the heat-transfer factor f as a per-unit quantity is an interesting way of bridging the gap between the per-unit conception of the electrical engineer and the dimensionless-modulus conception of the heat transfer engineer.

Loading of Hydrogen-Cooled Generators at Elevated Gas Pressures

D. S. SNELL
MEMBER AIEE

Synopsis: This paper presents a study, based on calculations and tests, of the heating characteristics of hydrogen-cooled generators at elevated gas pressures, and discusses various criteria for determining the capability of generators at elevated pressures. It is shown that the assumption of constant temperature rise of the windings above cold gas temperature, as a basis for limiting the output at elevated hydrogen pressures (particularly the rise of the armature winding by embedded detector) is misleading, and that a more realistic basis of rating is the assumption of constant total temperature of the winding copper, for constant temperature of ingoing cooling water at different loads and hydrogen pressures.

OF THE many advantages obtained through the use of hydrogen as the cooling agent for electric rotating machinery, one of the most important is the ability to secure additional kilovolt-ampere output through an increase in the operating hydrogen pressure. Increasing the hydrogen pressure increases the hydrogen density, thereby increasing its capacity to absorb and remove heat so that increased kilovolt-ampere output may be obtained for the same temperatures of the windings. For most generators in service, the normal rating is specified at an operating hydrogen pressure of 0.5 pound per square inch gauge, while an increase of 15 per cent in kilovolt-ampere rating is given at 15-pound hydrogen pressure, and increases of from 20 to 25 per cent at hydrogen pressures of 25 or 30 pounds per square inch gauge are specified.

Although operation of generators at elevated hydrogen pressures now has become quite general, relatively little information on the operating characteristics of generators at elevated pressures has been published. Also, there does not as yet seem to be complete agreement among the various manufacturers of electric equipment as to the correct basis for estimating the capacity of a generator at elevated pressures. This paper represents an attempt to supply information of this type, and to offer data that may serve as a basis for estimating the gains in rating to be obtained from operation at elevated pressures. The practical limits to which the hydrogen pressure may be increased are indicated, and the use of elevated pressures to compensate for an increase in cooling water temperature, is discussed.

Since the output of a generator is limited mainly by the heating of its windings, this study begins with an analysis of the temperature rise of the windings of a typical generator at various loads and hydrogen pressures, confirmed by extensive tests. The maximum temperature rise of the armature winding copper is first calculated, from which the armature temperature rise as would be measured by an embedded temperature detector is estimated. It is shown by tests and calculation that the standard allowance for the temperature difference between armature copper and embedded detector, specified as 10 per cent of the observed temperature rise, may be considerably in error as applied to hydrogen-cooled generators operating at elevated loads and hydrogen pressures.

From these calculations, supported by test data, the output of a generator at elevated hydrogen pressures, as limited by the temperature rise of the armature winding, has been calculated. A similar analysis is then made with respect to the rotor winding. It is shown, however, that the assumption of constant temperature rise of the windings as a basis for determining the output of a generator at elevated pressures, is unrealistic, since the temperature of the cold gas does not

Y., January 30–February 3, 1950. Manuscript submitted October 27, 1949; made available for printing December 22, 1949.

D. S. SNELL is with the General Electric Company, Schenectady, N. Y.

The author wishes to express his thanks to H. D Taylor, C. E. Kilbourne, and B. M. Cain for their interest in the preparation of the paper and for their many constructive suggestions; and to W. J. Gilson, J. H. Carter, C. H. Holley, and J. L. Bialous for their careful work in conducting the tests and analyzing the test data, on which many of the conclusions in the paper are based.

Figure 2. Thermal circuit of unit section of generator stator

Arrows show paths of heat flow

remain constant but increases appreciably, as the load and hydrogen pressure are increased.

It is suggested, therefore, that a better basis for determining the output of a generator at elevated pressures is the stipulation of constant total temperature of the winding, with constant temperature of the ingoing cooling water maintained. On this basis, curves are prepared showing the output of a generator at elevated hydrogen pressures as limited by the total temperatures of the armature and field winding copper. It is shown that in most cases the output of a generator will be limited by the heating of the armature copper, rather than by the heating of the rotor winding.

Figure 4. Calculated increase in cold gas temperature with increasing load and hydrogen pressure for 83,000-kw 3,600-rpm generator

Armature Heating Characteristics of Generators at Various Hydrogen Pressures

Calculation of Maximum Temperature Rise of Armature Winding Copper

In this section the maximum temperature rise of the armature winding copper of an 83,000-kw 3,600-rpm generator (rating at 1/2 pound* hydrogen pressure) has been calculated, for various generator loads at 0.85 power factor and at different hydrogen pressures. The method of temperature analysis developed by Soderberg[1] has been used for this calculation, considering a unit section of the armature conductor located in a discharge section of the core near the center of the generator. The influence of axial heat flow on the temperature rise of the conductor has been neglected, owing to the considerable length of the core, and the uniform cooling along its length obtained with the multi-

* Throughout paper, "pounds of pressure" indicates pounds per square inch gauge.

ple-flow system of ventilation employed.

The unit section of the armature is illustrated in Figure 1, and the thermal circuit for this section is shown in Figure 2. The various thermal resistances in this circuit are defined, and equations for their calculation are given in Appendix I. The terms q_b, q_c and q_t in Figure 2 represent the calculated losses in the core, winding, and tooth in the unit section, respectively. Solution of the equations for the thermal circuit gives the following relations

$$q_t = q_b N/M + (q_{bt} r_{tt} + q_c r_{ct}) r_t / M \qquad (1)$$

$$q_s = q_c S/M - (q_{bt} R_t + q_t R_t) r_t / M \qquad (2)$$

$$q_2 = q_{bt} + q_b - q_t \qquad (3)$$

$$\theta_s' = q_b r_4 + q_2 r_3 + \theta_g \qquad (4)$$

$$\theta_s = \frac{235 + T'}{235 + T' - q_b r_4} \times \left((\theta_g + q_b r_3 + q_b r_4 \quad \frac{(235 + T_a)}{(235 + T')} \right) \qquad (5)$$

where $q_{bt} = q_b + q_t$ and the other terms are defined in Appendix I. To calculate the temperature rise of the armature conductor θ_s from the foregoing equations, a value for T', the expected total temperature of the conductor, is first assumed, for which the copper loss q_c is calculated. Substituting the values of the various terms in the different equations, the value of θ_s', representing a first approximation of the temperature rise of the conductor, is calculated from equation 4, and the temperature rise corrected for change of loss with temperature, θ_s, then is determined from equation 5.

The value of θ_g, the temperature rise of the gas at entrance to the stator vent ducts of the unit section, is determined from analysis of the gas temperature rise in the gap between rotor and stator. Figure 3 gives the gap temperature rise from such an analysis, for the generator used for the example, for operation at rated load at 1/2-pound hydrogen pressure. As an approximation, the value of θ_g may in most cases be assumed equal to the total temperature rise of the gas through the generator, as determined from the losses and gas flow.

In calculating the thermal resistances of the thermal circuit of Figure 2, values of thermal conductivity of the various substances as determined from laboratory tests, have been used. The conductivity values are independent of the hydrogen pressure, since, although the presence of hydrogen in the insulation voids and between the stator laminations greatly improves the thermal conductivities of these materials over their values in air, there is no change in their conductivity with increasing hydrogen pressure, as the thermal conductivity of a gas is substantially independent of pressure.

In calculating the various surface thermal resistances, the heat transfer coefficients given in reference 2 have been applied. These coefficients are shown to be proportional to approximately the 0.75 power of the absolute hydrogen pressure, hence a considerable reduction in the values of surface thermal resistance with increasing hydrogen pressure, is obtained. The values of gas velocity over the various surfaces, used in estimating the values of the surface heat transfer coefficients, were obtained from the duct section areas, the measured rate of gas flow through the

generator, and from the distribution of gas flow to the various ducts determined from model tests.

In calculating the values of copper temperature rise (θ_c) from equation 5, two different bases of calculation have been used; one, based on an assumed constant temperature of inlet gas at all loads and hydrogen pressures; the other, based on constant temperature of water to the gas cooler, and constant water flow, under all load and pressure conditions. For the latter assumption, the values of inlet gas temperature have been calculated for the 83,000-kw generator for different loads and different hydrogen pressures from the equations given in Appendix II, and are shown in Figure 4. The increase in cold gas temperature which is shown to occur with increasing hydrogen pressure is the result of the reduction in temperature rise of the gas through the generator with increasing pressure (due to the increased gas density), which tends to reduce the

Figure 11. Estimated per-unit kilovolt-ampere output at 0.85 power factor at different hydrogen pressures for an 83,000-kw 3,600-rpm generator based on assumptions of constant temperature rise and constant total temperature of armature and field windings, from calculations

Figure 12. Estimated per-unit kilovolt-ampere output of several generators at rated power factor at different hydrogen pressures for assumption of constant temperature rise of armature winding by embedded detector, from tests

temperature difference from gas to water; so that an increase in cold gas temperature must occur in order to obtain sufficient temperature difference between average gas and average water temperatures to transmit the generator losses.

In Figure 5(A) are given the values of armature copper temperature rise above an inlet gas temperature assumed constant at 40 degrees centigrade, as calculated from equation 5 for the 83,000-kw generator operating at various loads from 1.0 to 1.4 times normal at 0.85 power factor and at hydrogen pressures from 1/2 to 50 pounds per square inch gauge.

Influence of Hydrogen Pressure on the Different Components of Armature Rise

In order to evaluate the influence of hydrogen pressure on the temperature rise of the armature winding copper, the different components of this temperature rise, calculated along a given heat flow path (together with the calculated total temperature rise above inlet gas temperature) are shown in Figure 6 for different generator loads, with hydrogen pressure as the independent variable.

For this analysis, the temperature rises of the armature winding copper have been calculated from equation 4, using assumed values for T', the total temperature of the copper, based on values for the temperature of inlet gas T_a as given by the curves of Figure 4. For the heat flow path axially to the tooth duct the components of the temperature rise θ_s' are as follows:

1. Temperature drop in coil insulation $q_b r_4$.
2. Temperature drop in iron across laminations $q_s r_{12} \alpha / r_{12}$.
3. Temperature drop at surface of vent duct, $q_s r_4 \beta / r_{12}$.
4. Temperature rise of gas at entrance to tooth duct, θ_g.

As shown in Figure 6, the temperature drop in the coil insulation is the largest of the several drops, and is practically unaffected by hydrogen pressure, decreasing very slightly with increasing pressure at a given load, and only as the result of decreasing copper loss with decreasing temperature. The gas rise in gap θ_g is shown to be, at low hydrogen pressures, the next largest of the temperature components, and to decrease rapidly with increasing pressure, being almost inversely proportional, at a given load, to the absolute hydrogen pressure. The temperature drop in the stator tooth is the next largest drop and is practically independent of hydrogen pressure. The surface temperature drop is shown as the smallest of the several drops, and is about inversely proportional to the 0.76 power of the absolute hydrogen pressure.

The dashed curves in the lower part of Figure 6, representing the increase in cold gas temperature above 40 degrees centigrade, with increasing hydrogen pressure and load, have been replotted from Figure 4 for comparison with the curves of the different components of armature temperature rise. It is shown that the influence of hydrogen pressure in reducing the surface temperature drop is practically cancelled by the increase in cold gas temperature caused by increasing pressure.

A study of Figure 6 shows clearly why the gain in output of a generator per pound increase in hydrogen pressure, falls off with increase in pressure, the components of armature temperature rise which are most influenced by hydrogen pressure

Table I. Hypothetical Load Capacities of Eight Generators of Various Ratings at 15 Pounds Per Square Inch Gauge Hydrogen Pressure

These Capacities Are Limited by (A) Armature, Temperature Rise by Embedded Detector; (B) Field Winding, Temperature Rise by Resistance, as Determined from Tests

Generator Number	1	2	3	4	5	6	7	8
Constant Armature Heating								
Rpm	3,600	3,600	1,800	3,600	3,600	1,800	3,600	1,800

* These output values are considerably higher than are obtained for constant temperature rise of armature copper and cannot therefore be considered as a proper basis of rating.

** Data obtained not reliable.

being shown to decrease rapidly with increase of pressure, to a point where they become small in comparison with the temperature drops which are independent of pressure.

Comparison of Calculated Armature Temperature Rises with Values Obtained from Tests

In Figure 7 the temperature rises of the armature winding copper of the 83,000-kw generator as calculated in a previous section for hydrogen pressures of 1/2, 15, and 25 pounds per square inch gauge are shown for different values of per-unit loss intensity on the armature coil surface, together with the temperature rises by embedded detector obtained from tests. (The shape of the calculated curves of temperature rise of armature winding copper was made to correspond with that of the curves of observed temperature rise, by using a value of thermal resistivity for the winding insulation 10 per cent above the value determined from laboratory tests which may be assumed as accounting for slot fit. Also, 1 degree was deducted from the calculated no-load temperature rises at 15 and 25 pounds pressure to obtain agreement with test values.) Deducting the observed temperature rises from the calculated rises of the armature copper, in Figure 7, at constant loss intensities, gives curves of temperature difference from copper to between-coil detector, at the above hydrogen pressures, as shown in Figure 8. Projecting and interpolating between the curves thus obtained, gives the curves shown for various hydrogen pressures up to 50 pounds per square inch gauge.

In Figure 8 are also shown curves of calculated temperature drop in the coil insulation and of the theoretical temperature difference between copper and a thermocouple-type embedded detector, the latter values being calculated by the method given in reference 3. The curves of temperature difference in Figure 8, as estimated from the calculated and test values of Figure 7, are observed to lie between the limits given by the above two curves. This result is due to the appreciable width of the temperature detector and the cooling of its edges by the gas flowing in the vent ducts.

In order to compare the values of temperature difference between calculated copper temperature and observed temperature, shown in Figure 8, with values of this difference obtained from actual tests made with thermocouples directly on the copper, Figure 9 has been prepared, giving values of this temperature difference as obtained from tests on a 35,300-kva air-cooled generator, and on a 6,250-kva experimental generator tested in both air and hydrogen,[4] the differences being shown, for convenience, for different values of per-unit loss intensity referred to normal intensity for the 83,000-kw generator used in the example. A considerable similarity will be noted between the curves of temperature difference obtained by actual tests and the estimated curves of Figure 8, the curves from the tests on the 6,250-kva generator showing a comparable increase in temperature difference with increasing hydrogen pressure, and also lying between the curves for theoretical temperature difference for a thermocouple-type detector, and calculated temperature drop in the insulation. The increase in temperature difference with increasing hydrogen pressure is believed due to the increased cooling effect of hydrogen at elevated pressures on the edges of the temperature detector, causing the detector to read lower, at a given coil loading, the higher the hydrogen pressure.

The foregoing analysis indicates good agreement between the calculated and observed temperature rises for the armature of the 83,000-kw generator, for the hydrogen pressures at which the tests were conducted; hence, confidence in the calculated values of armature copper temperatures at hydrogen pressures above the test values is justified. Greater confidence in the calculated temperature rises could, of course, be had if additional and more accurate test data on the temperature drop from armature copper to embedded detector at various hydrogen pressures were available.

Calculation of Maximum Temperature Rise of Armature Winding by Embedded Detector

Accepting the estimated values of temperature drop from armature copper to embedded detector as given by Figure 8 as reasonably accurate for the 83,000-kw generator, these values have been used in conjunction with the curves of calculated temperature rise of armature copper given in Figure 5(A) to obtain corresponding curves of temperature rise of embedded detector at various loads at 0.85 power factor and at various hydrogen pressures, as shown in Figure 5(B). The curves in this figure for 1/2, 15, and 25 pounds hydrogen pressure correspond with the test curves of Figure 8; the other curves are calculated.

Axial Temperature Distribution in Armature Conductor at Different Hydrogen Pressures

While the maximum temperature rise of the armature winding is of main importance in limiting the output of a generator at elevated hydrogen pressures, the axial temperature distribution along the conductor is of interest, especially since this distribution as obtained from tests on a number of generators at different hydrogen pressures, tends to confirm the accuracy of the analysis of the copper temperature rise given in the section on Calculation of Maximum Temperature Rise of Armature Winding Copper. In Figure 10 are shown the temperature rises of the various between-coil detectors located in the stator winding of the 83,000-kw generator as measured in tests at different loads and hydrogen pressures. It is shown that increasing the hydrogen pressure reduces the temperature differential between the detectors in the center of the stator and those near the ends, which may be explained by reference to Figures 3 and 6. In Figure 6 it is shown that at 1/2-pound hydrogen pressure, the gas temperature rise at center of gas gap is one of the largest components of the total temperature rise of armature copper. Re-

ferring to Figure 3, the gas rise in the gap for the end section of the generator is less than half of its value at the center, hence the temperature rise of the winding at the ends is correspondingly less. With increasing load and increasing hydrogen pressure, however, the temperature drop in the coil insulation becomes the predominating influence in the temperature rise of the winding. Since the rise in the gas gap becomes smaller at elevated pressures, there is less temperature difference in the gap axially, hence the temperature of the winding also, axially, is more uniform.

Calculation of Maximum Total Temperature of Armature Winding

In estimating the gain in output of a generator that may be obtained through increasing the hydrogen pressure, it is often assumed to be proper to limit the output at elevated pressures to values that will give the same temperature rises of the windings above inlet gas temperature as are obtained at rated load at 1/2-pound hydrogen pressure. This basis of rating, however, is somewhat fictitious, since the temperature of the inlet gas cannot usually be held constant, but increases with increasing load and hydrogen pressure. Since the actual winding temperatures, more than their temperature rises, determine the thermal deterioration of the insulation, a more realistic basis of rating would appear to be one which specifies the same total temperatures of the windings at all hydrogen pressures. In order to obtain an estimate of the gain in output of a generator to be obtained on the latter basis, the total armature copper temperatures of the 83,000-kw generator have been calculated for various loads at 0.85 power factor and at various hydrogen pressures, by adding to the values of T_a given by Figure 4 the values of copper temperature rise calculated from equation 5 for these values of T_a, giving the curves shown in Figure 5(C).

Similar curves for total temperature of the armature winding by embedded detector, at different loads and hydrogen pressures, have been derived from the curves of total maximum copper temperature given in Figure 5(C), by deducting therefrom the estimated temperature differences between copper and embedded detector given in Figure 8, giving the curves shown in Figure 5(D).

Estimated Generator Output at Elevated Hydrogen Pressures as Determined by Heating of the Armature Winding

In the foregoing section the maximum temperature rise and maximum total temperature of the armature winding, as would be measured by thermocouples on the winding copper and by temperature detectors between coils, have been calculated for an 83,000-kw generator for various loads and at various hydrogen pressures. These calculations are summarized in Figure 5. A horizontal line drawn through the resultant curves in each figure at the temperature or temperature rise for rated load at 1/2-pound hydrogen pressure, intersects the curves at points which give the loads which may be carried at various hydrogen pressures for constant armature temperature or temperature rise. Plotting these load points against hydrogen pressure gives the curves in Figure 11, showing the output at 0.85 power factor for 83,000-kw generator that may be obtained at different hydrogen pressures at constant temperature rise or constant total temperature of the armature winding. It will be observed that if criterion of constant temperature rise of hottest temperature detector be used, this gives higher permissible values of loading with increasing hydrogen pressure, than any of the other criteria; whereas the criterion of constant total temperature of the armature winding copper gives much lower permissible values of output. Also, whereas the curves of output calculated on the basis of constant temperature or temperature rise of the armature by embedded detector indicate no limit to the gains to be obtained by increasing the hydrogen pressure, the curves of output calculated for constant temperature or temperature rise of the armature copper tend to approach limiting values with increase in hydrogen pressure.

If it should be thought that the criterion of constant total temperature of the armature copper is too conservative a basis for determining the output of a generator at elevated pressures, one should note that no mention has been made of the increase in differential expansion between copper and iron which occurs at increased loads, as the result of the increased temperature drop in the insulation, and which may act to limit the life of the armature winding. If this item should be considered, the above criterion may be found to be actually not conservative enough. To indicate the magnitude of this item, the temperature drop in the armature insulation has been calculated for the 83,000-kw generator at the values of output given by curve 4 in Figure 11, and is shown as the single dashed curve in Figure 6. This curve shows an increase of 34% in the insulation temperature drop at 15 pounds pressure, and 43 per cent at 25 pounds.

While the curves given in Figure 11 have been calculated for a generator of modern design, and serve to illustrate the differences in output of a typical generator at elevated hydrogen pressures as specified by the various criteria presented, the actual values of per-unit output given by these curves will not necessarily apply to all generators, due to the variations in design that may exist. To evaluate the influence of differences in generator design on the gains in output at elevated hydrogen pressures, as specified by the several different criteria presented above, would be very laborious; however, an approximate evaluation of the influence of design differences may be obtained by comparison of the gains in output at elevated pressures for a number of representative generators on the basis of constant temperature rise of hottest armature temperature detector above inlet gas tem-

perature—admittedly an improper basis of rating, but a convenient, and fairly accurate basis of comparison. This has been done in Table I and Figure 12 in which the gains in output on this basis have been calculated from tests on eight generators of different ratings. It will be observed that for some of the generators, the outputs calculated on the basis of constant temperature rise of armature temperature detector are appreciably higher than for the 83,000-kw generator, while for others the outputs are less. These differences may be attributed partly to differences in the details of construction of the different generators, but must be considered as principally due to the differences in the normal temperature rise. For example, referring to Figure 7, if the normal 1/2-pound pressure rating of the 83,000-kw generator had been such as to give a temperature rise by hottest temperature detector of 40 degrees centigrade instead of 51.5 degrees centigrade, the per-unit loss intensity on the armature coil surface would have been 0.635 instead of unity, corresponding approximately to 80 per cent of normal rating. For the same temperature rise of the hottest detector in operation at 15-pound hydrogen pressure, the test curve in Figure 7 indicates that a loss intensity of 1.24 could be carried, corresponding approximately to 1.11 times normal rating. Hence the output at 15-pounds pressure, for 40 degrees centigrade rise of the hottest temperature detector, would be $1.11/0.8 = 1.39$ times normal, instead of 1.3, as estimated from the basis of a temperature rise of 51.5 degrees centigrade at 1/2-pound pressure at normal rating. Thus, the lower the temperature rise at 1/2-pound pressure and rated load, the greater is the output at elevated hydrogen pressures for constant temperature rise.

Rotor Heating Characteristics of Generators at Different Hydrogen Pressures

Calculation of Average Temperature Rise of the Rotor Winding

Depending on the design of a given generator, the heating of either the armature or the rotor winding may be the factor limiting the generator output at elevated hydrogen pressures. Having determined in the foregoing sections the output of generators as limited by the armature heating, a similar study will be made with respect to the heating of the rotor winding. In the present section an analysis of the average temperature rise of the rotor winding of the 83,000-kw 3,600-rpm generator used for an example above is made, for the generator operating at various loads and at different hydrogen pressures. In this analysis the rotor heating is assumed to be symmetrical about the transverse center line, and the half rotor is divided for calculation into several sections as shown in Figure 3. The temperature rises of the rotor end windings and of the three sections of the body are calculated separately and the average temperature rise of the entire winding then is calculated as the weighted mean temperature rise of the four sections.

The temperature rise of the rotor end windings, which are uninsulated, is calculated from conventional formulas. From the calculated losses in the end windings and the estimated rate of gas flow through the rotor body, the temperature rise of the gas entering the axial ventilating tunnels of the body is determined, which then is used in calculating the temperature rise of the body part of the winding.

The temperature rise of the body part of the rotor winding is calculated from equations given in Appendix III, which are based on the methods of analysis of Soderberg[1] and Peck.[5] A detail of a rotor slot of the 83,000-kw generator is shown in Figure 13, from which the thermal circuits shown in Figure 14 are derived. To simplify the calculation, it has been assumed that the losses generated in the slot for the section opposite the tooth tunnel pass to the tunnel and to the outside rotor surface, while the remainder of the slot loss passes to the subslot and to the pole center. The temperature rises of the outer and inner sections of the slot winding then are calculated independently and a weighted average rise for the two sections taken.

The method of calculating the temperature rise of the body part of the rotor winding from the equations in Appendix III is as follows. For a given section of the body the temperature rise in the gas gap T_g' is determined by analysis, see Figure 3. To this rise the surface temperature rises from pole face and friction loss are added, giving a fictitious gap rise, T_g. From the estimated gas velocities in the vent tunnels, heat transfer coefficients for these surfaces are calculated on the basis of inlet gas temperature, from equations given in reference 2. For the outer rotor surface the coefficients at different hydrogen pressures are determined by the method given in reference 2. From these coefficients the different surface thermal resistances of the thermal circuits of Figure 14 are calculated. The other thermal resistances are calculated from the slot and tooth dimensions and from values of thermal resistivity obtained from laboratory tests. For section 1 of the rotor body the gas rises T_{g1} and T_{g2} represent the rise of gas in passing through the rotor end windings.

Figure 16. Calculated temperature rise of a section of body part of field winding and the components of this rise for an 83,000-kw 3,600-rpm generator at different loads and hydrogen pressures. Outer coil section of number 2 longitudinal section of body considered

Curve (1): total temperature rise of winding. Curve (2): temperature drop in coil insulation. Curve (3): surface temperature drop in tooth tunnels. Curve (4): temperature rise of gas in tooth tunnels

For the other sections, their values are determined by adding to their values for the preceding section the calculated temperature rise of the gas in the vent ducts from the absorbed losses and rate of gas flow. Assuming a value for the expected total temperature of the conductor T', the losses in the slot W_1 and W_2 are calculated, and the temperature rises T_1' and T_2' calculated. The corrected rises T_1 and T_2 then are determined.

Using this method, the average temperature rise of the rotor winding of the 83,000-kw generator has been calculated for different assumed values of field coil loading at 0.85 power factor and at different hydrogen pressures, and the results are given in Figure 15. The curves obtained are approximately straight lines, intersecting the ordinate axis at a common point representing the heating of the rotor from windage loss. For comparison with the calculated values, values determined from tests on this generator at various hydrogen pressures

Figure 17 (below). Estimated per-unit kilovolt-ampere output at 0.85 power factor at different hydrogen pressures for an 83,000-kw 3,600-rpm generator, based on assumptions of constant temperature rise and constant total temperature of field winding, from calculations; also estimated output at rated power factor at different hydrogen pressures, for several generators, on assumption of constant temperature rise of field winding, from tests

Figure 18. Estimated per-unit kilovolt-ampere output at different power factors (lagging) at different hydrogen pressures, for an 83,000-kw 3,600-rpm generator, based on assumptions of constant total average temperature of field winding and constant total maximum temperature of armature winding copper

Solid curves show output limited by field heating. Dashed curve shows output limited by armature heating

also are shown. It will be noted that close agreement between test and calculated temperature rises is obtained for 1/2-pound and 25-pound hydrogen pressure, while for 15-pound pressure the test points fall somewhat below the calculated values, especially at the lower values of field coil loading. This may indicate inaccuracies in the calculation method, in the values used for the various thermal resistivities or heat transfer coefficients, or both. Considering, however, that the thermal circuits on which the equations for temperature rise are based are necessarily approximate, and that the gas velocities in the ventilating tunnels, on which the surface thermal resistances were based, were estimated, and not measured, values, the agreement between test and calculated values may be regarded as sufficiently close to justify confidence in the values of temperature rise calculated for hydrogen pressures beyond the range of the test values.

Influence of Hydrogen Pressure on the Different Components of Temperature Rise of Rotor Winding

As in the case of the armature winding temperature rise, it is useful to consider the temperature rise of the rotor winding also as separated into its several components, so that the influence of hydrogen pressure on the different components may be evaluated. For the rotor winding the temperature rise of the outer section of the conductor, for section 2 of the rotor body, will be considered for separation into its components, and the heat flow path to the tooth tunnel considered. (This particular section of the rotor winding was chosen for this analysis, since its calculated temperature rise was in most cases most nearly equal to the calculated average temperature rise of the entire winding.) The components of temperature rise for this path are:

1. Temperature drop in coil insulation, $W_1'R_{i1}$.

2. Temperature drop at surface of tooth tunnel, W_4R_{t1}.

3. Temperature rise of gas in tooth tunnel, T_{g1}.

In Figure 16, these components and the total temperature rise T'_1 are shown for two different generator loads and for various hydrogen pressures. As with the armature winding, the largest component of the temperature rise of the rotor winding also is the temperature drop in the coil insulation, which is independent of the hydrogen pressure. The surface temperature drop and the gas rise in the tunnel are shown to be about equal, and

Figure 19. Calculated cold gas temperature for 83,000-kw 3,600-rpm generator operating at rated load at various hydrogen pressures and with various temperatures of the water supplied to gas coolers. Constant water flow assumed

to decrease at about the same rate with increasing hydrogen pressure. Since the components of temperature rise of the rotor winding which vary with hydrogen pressure comprise a greater part of the total rise than is the case for the armature winding, the curves of total temperature rise of the rotor winding, shown in Figure 16, do not approach a limit with increasing hydrogen pressure as rapidly as do the corresponding curves for the armature winding, shown in Figure 6; hence the heating of the armature, rather than of the field winding, will limit the output of the generator at elevated hydrogen pressures.

Estimated Generator Output at Elevated Hydrogen Pressures as Limited by Rotor Heating

Output Estimated at Rated Power Factor

In Figure 15 giving the calculated average temperature rise of the rotor winding at different hydrogen pressures, for different loss intensities on the rotor coil surface, a horizontal line drawn through the temperature rise at rated load at 1/2 pound hydrogen pressure intersects the temperature rise curves in points which define the coil loading at the different pressures to give normal temperature rise above 40 degrees centigrade. Taking the square roots of the values of loss intensity thus determined, and referring to the load excitation curve for this generator (not included) gives the generator output at 0.85 power factor at different hydrogen pressures for constant temperature rise of the rotor winding above 40 degrees centigrade. These values are shown in Figure 17 for the different hydrogen pressures. Next, to determine the output at elevated hydrogen pressures at constant total temperature of the rotor winding, for an assumed constant rate of water flow to the gas cooler at 95 degrees Fahrenheit, the values of cold gas temperature from Figure 4 are added to the temperature rises of the rotor winding given by Figure 15, to determine the loss intensities on the field coil at different hydrogen pressures at which the total winding temperature equals 96.7 degrees centigrade, the total temperature at rated load 1/2-pound hydrogen pressure. The locus of these load points is shown in Figure 15 as curve B. Taking the square roots of these loss intensities and referring to the load excitation curve gives the values of generator output for constant total temperature of the rotor winding, which are shown as the lower curve in Figure 17.

In order to compare the gains in output at elevated hydrogen pressures for constant rotor heating, as calculated for the 83,000-kw generator, with values determined from tests on generators of various designs, output values estimated from tests on six other generators, based on constant temperature rise of the rotor winding, are shown in Figure 17; in Table I the output gains at 15-pound hydrogen pressure for these generators are shown. It will be noted from Figure 17 that the output curve for the 83,000-kw generator for constant temperature rise of rotor winding represents approximately an average for all the other generators; hence it may be considered as fairly representative. It also will be observed that the generator output at elevated hydrogen pressures, as limited by the temperature rise of the rotor winding, is practically independent of the temperature rise at 1/2-pound pressure and rated load, which is not the case if the output is limited by the armature heating. This difference follows from the fact that the no-load temperature rise of the armature winding, being due to both windage and core losses, decreases with increasing hydrogen pressure; while the no-load temperature rise of the rotor winding, being due to windage loss alone, is independent of the hydrogen pressure.

In Figure 11 the curves of generator output at constant rotor heating for different hydrogen pressures, for the 83,000-kw generator, as given by Figure 17, are shown in dashed lines for comparison with the curves calculated for constant armature heating. It will be noted that the output values calculated for constant rotor temperature or temperature rise are considerably higher than those based on constant temperature or temperature rise

of the armature winding copper, indicating that the heating of the armature copper rather than of the rotor copper, determines the output of this generator at elevated hydrogen pressures. However, if the output should be based on constant observed temperature or temperature rise, for both rotor and stator, the curves show that the heating of the rotor winding would limit the output of the generator at elevated pressures.

Referring to Table I, showing estimated gains in output at 15-pound hydrogen pressure for generators of different capacities, based both on rotor temperature rise and also on observed temperature rise of the armature winding, it will be noted that on these two bases of rating the rotor heating would limit the output at elevated pressure in the majority of cases. However, comparing the outputs for the 83,000-kw generator as given by curves 1 and 4 and Figure 11, and assuming this relation would apply approximately to the generators listed in Table I, it is probable that on the basis of constant total temperature of the winding copper, the armature heating would in all cases limit the output at elevated pressures, rather than the rotor heating.

Output Estimated at Less than Rated Power Factor

In many cases, it is desirable to utilize increased hydrogen pressures to obtain additional reactive kilovolt-ampere capacity from the generator, which involves operation at less than the rated power factor. Under these conditions, the heating of the rotor winding rather than that of the armature winding, will usually determine the output which may be carried. To determine the influence of power factor on the output of a generator at elevated hydrogen pressures, the output of the 83,000-kw generator as determined for constant total temperature of the rotor winding has been calculated for different power factors as shown in Figure 18. For this calculation the load excitation curves for the generator at different power factors have been used in conjunction with Figures 4 and 15. In Figure 18 the dashed curve shows the generator output as calculated for constant total temperature of the armature winding copper, which has been replotted from Figure 11. Actually, the output as limited by armature heating will be reduced somewhat as the power factor is decreased, due to the increased temperature rise of the gas through the generator from the increased rotor I^2R loss, but this reduction is relatively small, and is here neglected.

Reference to Figure 18 shows that at 0.8 power factor, the generator output is limited by rotor heating at all hydrogen pressures below 11 pounds; above this pressure the output is limited by the armature heating. At 0.7 power factor, the rotor heating is shown to determine the generator output at all hydrogen pressure below 24 pounds; while at 0.5 power factor the rotor heating is shown to determine the output at all pressures below about 60 pounds.

The Use of Increased Hydrogen Pressure to Compensate for Increased Temperature of the Water Supplied to the Gas Cooler

In some localities, the temperature of the water supplied to the gas cooler of a generator may exceed its normal value during certain periods. With an air-cooled generator, such a condition would require a reduction in generator output in order to maintain normal total temperatures of the windings. With hydrogen cooling, however, an increase in water temperature can usually be compensated for by an increase in the hydrogen pressure, causing a sufficient reduction in the temperature rises of the windings to maintain constant total temperatures even though the cold gas temperature has increased. In order to determine the amount by which the hydrogen pressure in a generator must be increased to permit normal output to be carried with no increase in total temperatures of the windings, with the temperature of the cooling water increased above normal, calculations have been made for the 83,000-kw generator used as an example previously.

Figure 20 (left). Calculated maximum total temperature of armature winding copper and average total temperature of field winding at rated load at different hydrogen pressures and different temperatures of the water supplied to the gas coolers, for an 83,000-kw 3,600-rpm generator. Constant water flow assumed

Curve (a): maximum temperature of armature copper. Curve (b): average temperature of field winding. Lines A–A = loci of water temperature points giving winding temperatures obtained at 0.5 pound per square inch gauge hydrogen pressure with 95 degrees Fahrenheit cooling water

Figure 21. Calculated allowable increase in temperature of water to gas coolers above 95 degrees Fahrenheit (at constant water flow) with increasing hydrogen pressure, for an 83,000-kw 3,600-rpm generator operating at rated load, with total temperature of either armature or field winding copper held constant

In these calculations the temperature of the cold gas is first determined, from the equations in Appendix II, assuming normal rated load at various hydrogen pressures, and with various temperatures of the ingoing cooling water. The calculated temperatures for the generator are shown in Figure 19. Equation 5 is used for calculating the temperature rise of the armature copper θ_s at rated load and at different hydrogen pressures, using the values of T_a from Figure 19. The total temperatures of the armature copper determined from these calculations ($\theta_s + T_a$) then are plotted against temperature of ingoing cooling water, as in Figure 20(A) and a horizontal line drawn through the resulting curves corresponding to normal temperature at 1/2-pound pressure with 95 degrees Fahrenheit cooling water. The intersections of this line with the calculated curves gives the temperatures of the cooling water at the various pressures for constant total armature copper temperature. Deducting 95 from these temperatures gives the solid curve shown in Figure 21 representing the permissible increase in water temperature for different hydrogen pressures, at constant armature copper temperature.

A similar calculation is made for constant total temperature of the rotor winding, using the curves of rotor heating given in Figure 15. By a process of cut-and-trial, in which, for a given assumed value of inlet water temperature and a given hydrogen pressure, the value of loss intensity on rotor coil surface is determined from the foregoing figure, giving a temperature rise which, when added to the proper value of T_a from Figure 19, gives a total temperature of the rotor winding which, for normal field current, gives the loss intensity initially assumed—curves of total temperature of the rotor winding for different water temperatures and different hydrogen pressures are derived, as shown in Figure 20(B). A horizontal line drawn through these curves corresponding to normal total rotor winding temperature for 95 degrees Fahrenheit water, intersects the curves at points giving the temperatures of cooling water at different pressures for constant total rotor temperature. Deducting 95 from these values gives the dashed curve in Figure 21, representing the permissible increase in water temperature for different hydrogen pressures, for constant rotor winding temperature.

Figure 21 shows that for the 83,000-kw generator, operating at hydrogen pressures up to about 15 pounds, the calculated permissible increase in inlet water temperature at constant load, for constant total temperature of either armature or field winding copper, is about 1.5 degrees Fahrenheit per pound increase in hydrogen pressure. At pressures above about 15 pounds, however, the permissible increase in water temperature per pound increase in pressure steadily decreases, being somewhat less for the condition of constant armature temperature than for constant field temperature.

While the calculated value of permissible increase in water temperature with increasing hydrogen pressure given for the 83,000-kw generator in Figure 21 cannot be assumed to apply to all generators, they may, however, be assumed to be fairly representative, since the curves of output for different hydrogen pressures for this generator, as limited by stator and rotor heating respectively, given in Figures 12 and 17, appear to be fairly representative.

Conclusion

It has been shown here that the basis often used for estimating the output of a generator at elevated hydrogen pressures, by which the output is limited by the observed temperature rise of the armature and field windings above the temperature of the inlet gas, is misleading and may result in operation of a generator at elevated pressures with actual temperatures of the winding copper considerably in excess of those which are obtained at 1/2-pound hydrogen pressure. It is suggested, therefore, that the total temperatures of the windings, based on constant temperature and flow of water to the gas cooler, be used as the basis for determining the output of a generator at elevated hydrogen pressures. It also is suggested that the maximum temperature of the armature winding copper, as estimated from the temperature detector readings, rather than the temperatures as given by detectors alone, be used in estimating the generator output as limited by armature heating. This will involve obtaining information on the temperature drop from copper to embedded detector more accurate than is now available, and an investigation of this type is suggested.

The principal results of this investigation are summarized in Figures 4, 6, 11, and 21. If the criterion of constant total temperature of the winding copper is accepted for the determination of the output of a generator at elevated hydrogen pressures, and if it may be assumed, as seems likely, that in most cases the output will be limited by the armature heating rather than by the rotor heating, the calculated curve 4 in Figure 11 may be used as a general guide for determining the gain in output of a generator at elevated hydrogen pressures.

Appendix I. Equations for Thermal Resistances Used in Calculation of Temperature Rise of Armature Winding

Nomenclature

T_a = temperature of gas entering generator fans

T' = assumed temperature of armature copper, for use in calculating I^2r loss

θ_g = temperature rise of gas at center of gap between rotor and stator = total gas rise through generator

θ_s' = temperature rise of armature winding copper as determined for I^2r loss calculated at temperature T'

θ_s = temperature rise of armature copper, corrected for change of I^2r loss with temperature

δ_i = thermal resistivity of outside coil insulation

δ_{ci} = internal thermal resistivity of coil radially

δ_f and δw = thermal resistivities of driving strip and wedge, respectively

δ_{iz} and δiy = thermal resistivities of iron across and along lamination, respectively

$\sigma_g, \sigma_{td}, \sigma_{bd}, \sigma_{bf}$ = surface thermal resistivities for gap, tooth duct, core duct, and core back surfaces, respectively

q_0, q_c, q_t = core loss, copper loss, and tooth loss, respectively, per slot and package

q_1 to q_6 = losses flowing along paths shown in Figure 2

A_{bd}, A_{td}, A_{bf} = surface areas of core and tooth ducts including spacers, and core back, respectively

A_{cd}' = surface area of coil sides in duct

A_{tg} = surface area of tooth tip

A_{bz} and A_{by} = cross-section areas of core for axial and radial heat flow, respectively

A_{cd} and A_{ci} = cross-section areas of insulation in duct and slot, respectively

A_{tz} and A_{ty} = cross-section areas of tooth for axial and radial heat flow, respectively

A_{cy} = cross-section area of wedge for radial heat flow

Temperatures and temperature rises are given in degrees centigrade, thermal resistivities in degrees centigrade inches per watt, surface thermal resistivities in degree centigrade square inches per watt, areas in square inches, losses in watts. Surface resistivities are reciprocals of surface heat transfer coefficients. Refer to Figure 1 for dimensional symbols.

Equations:

$$r_{cd} = \frac{\sigma_{si}}{A_{cd}} + \frac{\sigma_{id}}{A_{cd}'}; \quad \sigma_{si} = b\delta_i$$

$$r_{cy} = \frac{b'\delta_i + C\delta_f + d\delta_w + \sigma_g}{A_{cy}} + \frac{h_1\delta_{ci}}{3_{21}X_c}$$

$$r_b = \frac{r_{cd}\sigma_{cy}}{r_{cd} + r_{cy}}; \quad r_{tz} = \alpha + \beta$$

$$\alpha_1=\frac{\delta_{1z}}{12A_{1z}},\ \beta=\frac{\sigma_{1d}}{A_{1d}};\ r_{1z}=\frac{\delta_{1y}Y_1}{3A_{1y}}+\frac{\sigma_y}{A_{1z}}$$

$$r_{2z}=\frac{r_{1z}r_{1y}}{r_{1z}+r_{1y}};\quad r_{b2}=\frac{\delta_{2z}Y_1}{12A_{b2}}+\frac{\sigma_{bd}}{A_{bd}}$$

$$r_{by}=\frac{\delta_{1y}Y_b}{3A_{by}}+\frac{\sigma_{bf}}{A_{bf}}\quad R_1=\frac{r_{b2}r_{by}}{r_{b2}+r_{by}}$$

$$r_4=\frac{\sigma_{st}}{A_{st}},\ R_3=\frac{\delta_{1y}}{9A_{1y}}+\frac{\delta_{1y}Y_b}{3A_{by}}$$

$$r_{s1}=r_4+r_3\quad r_{s43}=r_3+r_{s1}$$

$$R_{12}=R_1+R_3;\quad M=r_3r_{s1}+R_{12}r_{s43}$$

$$N=R_2r_{s43},\quad S=r_3(r_3+R_{12})$$

Appendix II. Calculation of Cold Gas Temperature for a Hydrogen-Cooled Generator

Nomenclature

A_o = over-all cooler heat transfer factor, kilowatts per degree centigrade log mean temperature difference gas to water

C = free cross-section area of cooler, square feet

d = density of pure hydrogen at temperature T_a' and atmospheric pressure, pounds per cubic foot

e = cooler efficiency, per cent (=100 for clean tubes)

G = hydrogen mass velocity through cooler, pounds per hour per square foot

G_o = water flow to cooler, gallons per minute

L_o = losses given to cooler, kilowatts

N = purity correction factor = (107.5-Z)/-7.5

P_a = hydrogen pressure, atmospheres

Q_o = gas flow through fans, cubic feet per minute

R = gas constant (degree centigrade per kilowatt at 1 cubic foot per minute) = 1,890 (273+T_a')/313 P_a

S = surface area of cooler, square feet

T_a' = average temperature of gas through fans, degree centigrade

T_1 = temperature of gas leaving cooler, degree centigrade

T_4 = temperature of gas entering cooler, degree centigrade

T_5 = temperature of water entering cooler, degree centigrade

T_6 = temperature of water leaving cooler, degree centigrade

U = over-all heat transfer coefficient for cooler tubes at 100 per cent efficiency, BTU per hour per square foot per degree Fahrenheit

Z = hydrogen purity per cent

Equations:

$$A_o=1.8e\ SU/341{,}500 \tag{6}$$

$$G=60Q_odNP_a/C \tag{7}$$

Let

$$T_1=T_4-T_6 \text{ and } T_2=T_1-T_5 \tag{8}$$

Then

$$T_1-T_2=T_4-T_5-(T_6-T_5) \tag{9}$$

Also

$$T_4-T_5=RL_o/Q_o \tag{10}$$

And

$$T_6-T_5=3.8\ L_o/G_o \tag{11}$$

Let

$$F_o=R/Q_o-3.8/G_o \tag{12}$$

Then from equation (9)

$$T_1-T_2=F_oL_o \tag{13}$$

Also

$$L_o/A_o=\frac{T_1-T_2}{2.3\log_{10}T_1/T_2} \tag{14}$$

Hence

$$\log_{10}T_1/T_2=F_oA_o/2.3 \tag{15}$$

Let

$$T_2=\frac{T_1-T_2}{T_1/T_2-1}\quad\text{and}\quad T_3=T_5+T_2$$

Then

$$T_3=T_5+\frac{F_oL_o}{T_1/T_2-1} \tag{16}$$

In order to calculate the cold gas temperature for a hydrogen-cooled generator from equation (16) for a given load and hydrogen pressure, the value of G is first determined from equation (7) and by reference to curves of over-all heat transfer coefficient U for different values of G at different water velocities in the cooler tubes, the correct value of U is determined. Assuming a value of efficiency e to take account of fouling of inside tube surfaces, the value of A_o is calculated from equation (6). Calculating the value of F_o from equation (12), the value of T_1/T_2 may be determined from equation (15) and the cold gas temperature T_3 may then be calculated from equation (16).

Appendix III. Equations for Temperature Rise of Body Part of Rotor Winding

Nomenclature

R_{i1} and R_{i2} = thermal resistances of side slot insulation, outer and inner sections of slot

R_m and R_n = radial thermal resistances of outer and inner sections of tooth

R_r = thermal resistance of tooth root

R_w and R_t = thermal resistances of coil wedge and tooth tip, respectively

R_3' = thermal resistance of iron path to pole center surface

R_{w2} and R_{t2} = surface thermal resistances of coil wedge and tooth tip, respectively

R_{i3} and R_{i4} = thermal resistances of insulation at top and bottom of slot, respectively

R_5 and R_7 = internal radial thermal resistances of conductor for outer and inner sections

R_{b3}, R_{s1}, R_{s2} = surface thermal resistances for underside of slot filler, tooth tunnel, and sub-slot, respectively, calculated on inlet temperature basis

R_{s3} = surface thermal resistance for pole center surface

S = resistivity constant of winding = 235 for copper, 225 for aluminum

T_a = temperature of gas entering fans

T' = assumed temperature of conductor for calculation of losses

T_1' and T_2' = temperature rise of outer and inner sections of conductor, calculated for losses W_1 and W_2

T_1 and T_2 = temperature rises T_1' and T_2' corrected for change in loss with temperature

T_f = temperature rise of rotor surface from friction loss

T_p = temperature rise of rotor surface from pole face loss

T_g' = temperature rise of gas in gap between rotor and stator

T_e = equivalent temperature rise of gas in gap = $T_g'+Tf+Tp$

T_{e1} = temperature rise of gas at entrance to tooth tunnel

T_{e2} = temperature rise of gas at entrance to subslot

W_2', W_2'', W_2''' = surface losses (friction and pole face losses) apportioned to wedge, tooth tip and pole face surfaces, respectively

W_1 and W_2 = losses in outer and inner section of coil, respectively, calculated at temperature T'

W_1'', W_2'' and so forth = components of W_1 and W_2 flowing along paths shown in Figure 14

Temperatures and temperature rises are given in degree centigrade, thermal resistances in degrees per watt, and heat flow in watts. One-inch axial length of rotor body is considered.

Equations:

$$R_3=R_3'+R_{s3},\quad R_4=R_w+R_{w2}+R_{i1}$$

$$R_{34}=R_3+R_4,\quad R_{10}=R_m+R_r+R_{i4}$$

$$R_{20}=R_{i3}+R_n+R_r,\quad R_{70}=R_7+R_{i3}+R_{b2}$$

$$R_{720}=R_{70}+R_{20},\quad A=T_o-T_{e1}$$

$$B=T_o-T_{e2},\quad C=R_{720}+R_{i2}$$

$$D=R_3+R_{s2},\quad E=R_{34}+R_{i1}$$

$$F=R_{10}+R_{s1},\quad G=A+R_{34}W_1$$

$$H=W_2T_{70},\quad J=EF+R_{10}R_{s1}$$

$$K=CD-R_{s2}^2$$

$$W_1'=(FG-AR_{s1})/J;\quad W_2'=(HD-BR_{s2})/K$$

$$W_4=(AE+GR_{10})/J;\quad W_7=(HR_{s2}-BC)/K$$

$$W_3=W_2'-W_7$$

$$T_1'=W_1'R_{i1}+W_4R_{s1}+T_{e1}=W_1''R_{i4}+T_o$$

$$T_2'=W_2'R_{20}+W_3R_{s2}+T_{e2}=W_2''R_{70}+T_{e1}$$

$$T_1=\frac{S+T'}{S+T'-(T_1'-T_{e1})}\times\left[T_{e1}+(T_1'-T_{e1})\frac{(S+T_a)}{(S+T')}\right]$$

$$T_2=\frac{S+T'}{S+T'-(T_2'-T_{e2})}\times\left[T_{e2}+(T_2'-T_{e2})\frac{(S+T_a)}{(S+T')}\right]$$

Discussion

V. V. Mason (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): The author goes through involved calculations based on a very much simplified equivalent thermal circuit of the windings and comes out with curves of the kilovolt-ampere output at various hydrogen pressures estimated on various criteria, Figure 11 of the paper. This figure indicates that the use of an embedded resistance-type temperature detector to control the loading of machines at elevated pressures will result in excessively high copper temperatures as calculated by the author's method. To support his calculations, the author gives his Figure 9, which shows excellent agreement between calculated and observed values for armature-coil surface losses of 0.5 per unit, but considerably poorer agreement (differences of the order of 50 per cent) at surface losses of 1.1 per unit. A surface loss of 1.1 per unit corresponds to a kilovolt-ampere output of $\sqrt{1.1}$ or approximately 1.05 per unit. Reference to Figure 11 shows that at a kilovolt-ampere output of 1.05 per unit, all methods of estimating the overload capabilities give very nearly the same results.

Even if the agreement between calculated and test values as shown in Figure 9 were exact, this would verify the curves of Figure 11 only at the 1.05 per unit kilovolt-ampere points. The lack of agreement between experiment and theory shown in Figure 9 makes even these points open to serious doubt. In effect then, it appears that the author has not been able to offer any convincing experimental confirmation of his calculations. Hence, it is suggested that his results be regarded as very pessimistic until such time as more complete experimental results are available.

I agree with the author that it is the total temperature of the windings which determines the permissible loading of the machine rather than the temperature rise. However, where there is a possibility of very low cooling-medium temperatures it may be wise to set a limit on the maximum allowable temperature rise to guard against excessive relative movement between copper and iron due to differential expansion.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The emphasis in this interesting paper on temperature of the copper conductors themselves in armature windings, in contrast to the usual reference to temperature of embedded armature detectors, seems to be a fundamental and necessary step in establishing load capabilities of generators. Of course, as the author indicates, this is particularly necessary for hydrogen-cooled generators when operating at the higher internal gas pressures. In general, however, the basic work on allowable temperatures, whether in regard to standard limits for various types of insulations or for various kinds of metal contacts, usually are (or should be, in my opinion) focused on the hottest temperature of the conductors involved. This applies, as is indicated by various AIEE articles and standards, particularly to insulated wires and cables, transformers, contacts of circuit breakers, bus-bar joints, and so forth.

In the third paragraph of the paper, the author refers to the "standard allowance for the temperature difference between armature copper and embedded detector" as being "specified as 10 per cent of the observed temperature rise." It would correspond at most to only 6 degrees centigrade (10 per cent of the standard limit of 60-degree rise by detector). However, the implication of the data in Figure 9 of the paper is that the temperature difference actually may be two or more times that amount for air-cooled machines and machines operating with hydrogen at 1/2 pound per square inch gauge. Comments on this point would be of interest.

Curve (*c*) of Figure 5 shows per-unit kilovolt-ampere output for various hydrogen pressures with a limit of about 101 degrees centigrade for armature copper. Is there an implication that this total temperature is satisfactory for safe operation throughout the life of generators? That temperature is materially less than allowed, in effect, by the usual limit of 60-degree centigrade rise by embedded detector, and is greatly less than permitted for class-*B* insulation when used in other apparatus; on the other hand, large modern machines generally have lower total temperatures at rated load than 101 degrees centigrade.

Loads on generators in service usually vary greatly each day. In connection with large machines, where the length of the armature coils may be, say, 22 to 25 feet it seems that the allowable daily temperature rise of the copper temperatures should be less than for relatively small generators. Otherwise the differential expansion between armature copper and iron may cause premature fatal weakening of the insulation.

The manufacturers apparently have recognized this point by designing very large machines for temperature rises measured by an embedded detector materially less than the standard limit of 60 degrees centigrade. The author mentions the point, but gives only a little discussion on it. Attention is drawn to it here because with hydrogen cooled machines operating at elevated gas pressures, that differential may be very large as compared to what has obtained for moderate-sized air-cooled machines which have operated without trouble for 25 to 30 years. For instance, according to Figure 6 of the paper, with a total armature-copper rise of 66 degrees centigrade at 20 pounds per square inch gauge hydrogen pressure for the given machine, the temperature drop in the armature coil insulation is about 40 degrees centigrade.

M. D. Ross and **R. A. Towne** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The calculations presented by Mr. Snell demonstrate qualitatively the reason hydrogen-cooled machines are rated and operated, at loads above the normal rating, on the basis of hydrogen pressure rather than temperature rise.

The calculation of the thermal circuit of an electric machine requires a complete analysis of the thermal circuit, an accurate knowledge of the thermal constants involved, and a precise segregation of all load losses.

The segregation of losses is a particularly knotty problem. Improper loss segregation can lead to appreciable errors in the temperatures calculated. Because of the difficulties involved in a temperature calculation of this nature, we believe that extensive copper temperature measurements should be secured to calibrate the calculations.

The behavior of temperature detectors in air has been studied,[1] but the effect of hydrogen on detectors has not been determined precisely, although the low temperature rises obtained during operation at elevated gas pressures indicate an obvious discrepancy.

Among the factors involving detector accuracy are:

1. Variation in eddy loss between top and bottom strands in the slot.

2. The effect of slot geometry and slot insulation thermal characteristics on the heat-flow path in the vicinity of the detector. The ratio of insulation thickness to slot width and the ratio of lateral to transverse thermal conductivity of the stator winding insulation are principal factors determining the heat-flow path.

3. The effect of the ventilating gas on the detector. The ventilating gas can cool the detector in two ways.

a. The radial flow of gas cools the edges of the detectors exposed in the vent spaces between packs of punchings.

b. An axial flow of gas along the clearance space between the edge of the detector, the rounded corner of the stator coils, and the slot side cools the edge of the detector along its length normally considered to be blanked off by the punchings. Since the lateral thermal conductivity of the detector material may be several times higher than the transverse conductivity, this cooling effect is considerable.

These cooling mechanisms are functions of the gas temperature in the immediate vicinity, the radial velocity, the gas pressure, the differential pressure across the punching packs, and the ratio of the vent width to the pack thickness.

Although the effect of many of the previously mentioned factors is known, the quantitative effect of others, especially those involving the ventilating gas, is obscure at present.

Model tests made some time ago indicated, in general, the effects on the detector which have just been mentioned. We propose to make factory tests on several large machines with thermocouples built into the neutral coils in order to measure the copper temperatures and compare them with adja-

cent temperature detectors. With so many factors influencing the detector error, we do not believe that it is worth while attempting to calculate this factor.

We have realized for some time that hydrogen-cooled machines, when operated at elevated gas pressures, cannot be loaded safely on the basis of embedded-temperature-detector readings, as internal temperatures in the stator coils may be excessively high at the high gas pressures. We have advocated that such machines be loaded in accordance with the nameplate rating. Most of our machines are rated relatively 100 per cent at 0.5 pound per square inch gauge gas pressure, 115 per cent at 15 pounds per square inch gauge and, in some cases, 125 per cent at 30 pounds per square inch gauge. We are satisfied that copper temperatures of any of our machines, designed for higher gas pressures, when loaded according to this schedule will be satisfactory.

The subject of hot-spot allowances in hydrogen-cooled machines could well be investigated further by the interested AIEE committees so that uniform methods of approximating the copper temperatures can be standardized. If a suitable temperature detector, shielded from the cooling action of the gas, can be developed, it may be possible to approximate more nearly the copper temperature.

It would seem that Mr. Snell's conclusion that all hydrogen-cooled machines should be loaded according to some such schedule as shown in curve 4 of Figure 11 of the paper is somewhat premature in the light of present data.

Ever since hydrogen-cooled machines have been operated at pressures above atmospheric, it has been recognized that a cooler designed for 40-degree centigrade outlet gas temperature at 0.5 pound per square inch gauge will have an outlet temperature of 42 to 43-degree centigrade at 115 per cent load and 15 pounds per square inch gauge gas pressure. To obtain 40-degree centigrade outlet temperature at 15 pounds per square inch gauge would involve as much as 40 per cent more surface and a considerably larger generator frame. This matter was recognized in making up AIEE Standard Number 602[2] for hydrogen-cooled generators where the outlet gas temperature is specified as 40 degrees centigrade at 0.5 pound per square inch gauge and the ambient is allowed to go up at the higher pressures. We would agree with Mr. Snell that the ambient gas temperature be left out of the temperature guarantee for hydrogen-cooled turbine generators and that the temperature rise be established above cooling-water temperature.

Mr. Snell is to be congratulated on a very fine discussion of the factors involved in loading hydrogen-cooled machines. The paper is an important contribution to the literature on this subject.

Carl J. Fechheimer (Consulting Engineer, Milwaukee, Wis.): The explosion pressure increases with the density of hydrogen for an optimum mixture with air. If generators are designed to withstand such explosive pressure, is not the increased cost to be given serious consideration, particularly with large diameters intended for the higher ratings?

The statement that the heating of the stator, rather than the rotor, may be the limit, is surprising. Would that be the case for a generator that had been intended previously to operate at 1/2 pound per square inch gauge and later was operated at elevated pressure? Or one for which the tools had been made and could not readily be altered? If the designer can start with a clean slate and select new proportions throughout, would not the rotor be the limit, assuming that the generator is to operate at about 85 per cent power factor, and not less than 0.8 short-circuit ratio? Is there any reason why the stator slots cannot then be made of sufficient depth to accommodate enough copper to secure the desired temperature?

Mr. Snell's statement that the temperature determined by a detector in the armature read low recalls a paper of 30 years ago.[1] Reasons for the detector's low reading are brought out; a map of heat flow and isothermal lines explains most of it. The derivation by Wilhelm Peters[3] enables the engineer to determine what differences to expect. Peters gives a plot in a family of curves, from which the ratio of the temperature drop by detector to the total drop can be read.

Mr. Snell has done much valuable work in calculating temperatures and ratings. I spent considerable time some years ago in a study of Soderberg's paper[4] and in its applications. The method is tedious, even when the equivalent electric circuit is sub-

Figure 1. Coefficients of discharge in a turbine generator rotor vent duct

Figure 2. Calculated gas flow in a turborotor

stituted for the solution of the partial differential equations. In discussing the solution with Mr. Soderberg in 1931, he told me that one point that disturbed him was the location of the Surface of Division. Mr. Snell has located it in the rotor about halfway down in the slotted part. Then he calculated the temperature for each part and took a weighted mean. It would be interesting to learn about what percentage of error had been introduced by an inaccurate selection of the Surface of Division.

Another questionable point is the value of the surface heat-transfer coefficient where there are obstructions or sharp 90-degree turns in the fluid path. Studies that were made on enclosed ventilated motors, using an equivalent electric circuit, caused me to question results because there were uncertainties in some parts where obstructions entered and the flow was very complex.

Figure 1 of the discussion shows plotted data taken on a stationary model in which axial and radial rotor ducts of a turbine generator were simulated. The curve shows how the discharge coefficient varied with the ratio of axial to radial velocities.

Figure 2 of the discussion shows the calculated gas flow in a turborotor, for which data from Figure 1 were used. The calculations are rather long and tedious.

T. de Koning (Consulting Engineer, Philadelphia, Pa.): Mr. Snell has favored us with an excellent paper. He emphasizes that a constant total temperature of the winding copper, which, however, cannot be measured readily, forms a realistic basis for a proper determination of the load that can be carried. Furthermore, he brings out that the embedded temperature detectors of the windings give misleading information. It is shown that the output of a generator is limited by the heating of the rotor copper or by the armature copper, but mostly by the latter. It is brought out that every machine reacts differently to hydrogen-pressure increases in regard to per-unit kilovolt-ampere output, and it looks as if the hydrogen-pressure distribution over the length of the machine is of influence, too. We have seen from the many illustrations how the power factor, the water temperature, and the hydrogen temperature influence the permissible load.

The obvious conclusion is, either we have to be very conservative about loading machines working with elevated hydrogen pressures, or we need some kind of complicated device which takes care of the permissible load determination. The simple way out would be to run the machine continuously with maximum hydrogen pressure, but most public-utility engineers do not like this idea. They claim it would decrease the efficiency of the machine and increase the hydrogen losses.

Adding one more gadget to the many a hydrogen-cooled machine needs most likely will not be considered objectionable. They seem to be well designed, and as long as they function well one forgets about the complications. However, from a development-cost standpoint the picture is less rosy. After spending large amounts of money on the shell, the coolers, the seals, hydrogen-sealing equipment, hydrogen-purity equipment, rotor copper alloys, and so on, we now will need some for a permissible load determination device. The question arises: was the choice of hydrogen cooling the right one, and might not another method have been better?

F. M. Porter (American Gas and Electric Service Corporation, New York, N. Y.): Mr. Snell is to be complimented on his thorough analysis of the factors affecting temperature rises in the various parts of generator stators and rotors when operating at gas pressures ranging up to 50 pounds per square inch gauge. A much clearer picture is now available of what to expect in the way of increased capacity, either in the form of kilowatts or reactive kilovolt-amperes, when utilizing higher gas pressures than 1/2 pound per square inch gauge.

We have in operation on the system of the American Gas and Electric Company 22 hydrogen-cooled generators. The first one of these units to be installed was at Logan, West Virginia, and this machine has been in service over 12 years. Some of the older machines have been operated either continuously or intermittently at gas pressures ranging from 5 to 15 pounds per square inch gauge, and in the case of the four most recent units, placed in service in the last six months, we are operating them satisfactorily at a gas pressure of 25 pounds per square inch gauge. With reference to the 18 older units, gas pressure up to 15 pounds per square inch gauge was utilized primarily to obtain greater kilowatt capacity, particularly during the war and postwar periods. We also have used it to keep down field temperatures when increased reactive kilovolt-amperes were required in emergency or otherwise. In a few cases, where cooling-water temperatures above 100 degrees Fahrenheit sometimes occur, we have resorted to increased gas pressure to keep the machine temperatures within proper limits.

The author suggests that the total temperature of the windings be used as a basis for determining generator output at elevated pressures, partly because of increase in cold gas temperature which, in turn, is based on constant temperature of water to the coolers and constant water flow through the coolers. As far as we are concerned, constant water flow is not a practical basis for determining rating, since all of our machines have coolers designed to provide sufficient water flow to remove losses resulting from increased loading at high gas-pressure operation and still maintain cold gas temperature at 40 degrees centigrade or below. In general, because of this adequacy of the coolers, we are able to maintain cold gas temperatures between 30 and 35 degrees centigrade although occasionally, on very hot summer days, this temperature may go as high as 40 degrees centigrade. Therefore, we believe this factor should be taken into consideration in determining the permissible increase in capacity at higher gas pressures. Furthermore, since the cold gas temperature may be as low as 30 degrees centigrade, it is our understanding that the manufacturers recommend a loading based on temperature rise above this cold gas temperature rather than total permissible temperature, which would be based on a cold gas temperature of 40 degrees centigrade. We believe that, in the case of machines with relatively low temperature rises for field and/or stator at rated load, one should consider taking advantage of this fact to obtain increased capacity from the machine, on a temperature basis, in the same manner that increased volt-amperage is permissible because of the increased cooling effect at higher gas pressures.

Referring to Figures 12 and 17 of the paper, which have to do with increase of unit kilovolt-ampere output of generators at various gas pressures, we have found, in the case of a 43,780-kva 0.9-power factor 1,800-rpm generator, that the following increases are indicated for the temperature rise obtained from stator temperature detectors:

Output, Per Unit Kilovolt-Amperes	Hydrogen Pressure Pounds per Square Inch Gauge
1.11	5
1.18	10
1.24	15

Similarly, for the field of this machine, unit kilovolt-ampere increases are indicated as follows:

Output, Per Unit Kilovolt-Amperes	Hydrogen Pressure, Pounds per Square Inch Gauge
1.11	5
1.23	10
1.32	15

These match some of the representative curves shown in the paper. We also have found, in the case of a 110,000-kva 0.9 power factor 1,800-rpm machine, that the corresponding unit kilovolt-amperes at 15 pounds per square inch gauge are 1.41 for the stator and 1.42 for the rotor, indicating that both field and stator limit the loading at about the same point in so far as observed readings are concerned. The values stated in this paragraph for generators of different capacities, together with data on those included in Mr. Snell's paper, indicate that wide variations are to be expected and that general conclusions cannot be drawn for all machines. Therefore, the size, speed, normal temperature rise of parts at low gas pressure, and other factors are going to affect the decision as to what increased capacity can be carried.

As a matter of interest, we are including similar unit kilovolt-ampere output data for a typical 18,750-kva 900-rpm hydrogen-cooled synchronous condenser which has been operating at gas pressures up to 25 pounds per square inch gauge for approximately 10 years. Temperature runs made in 1941 indicated that, for similar field and stator temperature rises, based on an initial 18,750-kva run at 1/2 pound per square inch gauge gas pressure, the following per-unit-kilovolt-amperes would apply:

		Gas Pressure, Pounds Per Square Inch Gauge		
		10	20	25
Unit kilovolt-ampere increase	Field	1.14	1.24	1.30
	Stator	1.16	1.31	1.39

Obviously, in this case the field temperature rise is the limiting feature. We have been carrying loads on this unit, as well as on five other similar machines, based on these increases in so far as the field heating is concerned.

To return to the general problem of generators, it is indicated that observable field temperature rise is a reasonably satisfactory means for determining maximum loading in so far as rotor heating is concerned. However, it is not permissible to use the stator temperature rise as obtained from the resistance temperature detector because of the variation in differential between this observed temperature and actual copper temperature at higher gas pressures. Since operation at elevated gas pressures is being employed continuously on many of the older units, and probably will be employed on practically all new units, it is essential that agreement on loading limitations be reached with the manufacturers as quickly as possible so that the operating companies may keep within the limits of any given unit while relying on temperatures which can be obtained and read continuously. We believe it is going to be necessary to determine these limitations for each individual unit because of the many variables involved. Obviously, the information presented by Mr. Snell has been a great step forward in clarifying this problem of generator operation at elevated gas pressures.

D. S. Snell: Mr. Mason's criticism of the accuracy of the temperature calculations given in the paper appears to be the result both of failure to read the paper carefully and of unfamiliarity with the method of temperature analysis given. The calculation of the armature and field-winding temperatures given in the paper, using the thermal circuits shown in Figures 2 and 14 of the paper, is based upon a method of temperature analysis developed by C. R. Soderberg[1] which, since its introduction in 1931, has been used widely and has been proved to be remarkably accurate whenever the values of the thermal resistances and unit loss intensity are known accurately. Mr. Mason has, apparently without adequate analysis, suggested that the calculations of the armature temperatures by this method are highly inaccurate, while overlooking the fact that the application of the same method to the calculation of the temperatures of the field winding gave results which checked the test results very closely. Since a check on the calculated armature copper temperatures was not possible, it was necessary in the paper to make an estimate of the temperature drop from copper to detector based on tests on other machines. Mr. Mason has assumed that the measured temperature drops given by Figure 9(C) of the paper for a 6,250-kva generator should apply for the 83,000-kw generator used in the example. This is incorrect since the theoretical temperature difference between copper and an ideal detector is considerably greater for the 6,250-kva generator than for the generator used in the example. By comparing Figure 9(C), curve 2, with Figure 8, curve 3, one can see that the temperature difference from copper to an actual detector also should be greater. If this difference in design between the two generators is taken into account, the estimated temperature differences from copper to detector shown by curves 2 in Figure 8 for the generator used in the example do not appear to be unreasonable. It appears, therefore, that Mr. Mason's suggestion that the results are to be regarded pessimistically is quite unwarranted.

Mr. Halperin's comments on the inconsistency of the present standards for hottest spot allowance with available test data are very pertinent. The present AIEE Standard[2] for hottest spot allowance of 10 degrees centigrade at rated load for class-*B* insulation is apparently based on the ten-per cent rule mentioned in the paper, which specified an allowance based on ten per cent of the observed temperature rise in degrees centigrade rounded off to the nearest multiple of five above the estimated value. Tests on both hydrogen-cooled and air-cooled generators indicate actual temperature differences considerably at variance with this rule. As shown in Figures 8 and 9 of the paper, the actual temperature differences between copper and embedded detector lie somewhere between the calculated temperature drops in the coil insulation and the theoretical temperature differences between copper and an ideal detector of the thermocouple type, having no heat loss, and hence will be different depending on the design of the armature coil. As suggested in the paper, an experimental determination of the temperature difference between copper and embedded detector, for hydrogen-cooled generators of modern design, is much to be desired.

For the generator used in the example, the measured temperature rise of armature winding at rated load and hydrogen pressure of 1/2 pound per square inch gauge was 52 degrees centigrade, and the calculated temperature rise of copper was 61 degrees centigrade. For 40-degree centigrade inlet gas, a hottest spot temperature of 101 degrees centigrade is thus indicated. Since it is considered good practice to limit the observed armature temperature rise of turbine generators to 60 degrees centigrade, and since AIEE Standards permit a hottest spot temperature of 130 degrees centigrade, it is evident that this generator is conservatively rated and should have a high life expectancy.

It is true, as Mr. Halperin suggests, that as the sizes of generators increase, the increased length of the armature bars makes a lower temperature gradient in the insulation desirable. The increased temperature drop in the insulation obtained at overloads when utilizing elevated gas pressures to secure increased output increases the differential expansion between copper and iron and therefore reduces somewhat the life expectancy of the generator. The extent of this reduction depends on the frequency and extent of the overloading; however, since operating experience at elevated pressures has been relatively limited, it is not possible at present to state the extent to which the life of a generator is impaired by such operation.

The author is indebted to Mr. Ross and Mr. Towne for amplifying and clarifying many of the points made in the paper. Calculation of the heating of the armature and field windings for the generator used in the example, to the degree of accuracy obtained, was made possible through a complete analysis of the various losses, confirmed by tests. These tests included laboratory tests to determine the thermal conductivities of the insulation and the stator laminations in hydrogen, model tests to determine the amount of gas flowing through the different stator vent ducts, and analysis and tests on a generator rotor operated in the open to determine the gas flow through the rotor vent ducts. However, as pointed out by the discussors, temperature calculation is a difficult and complicated matter, and the checks given in the paper on the calculated copper temperatures are not as conclusive as the author would desire. Tests to determine the actual armature copper temperatures of hydrogen-cooled generators are greatly needed, and it is gratifying to note that such tests now are being undertaken.

The analysis of the factors influencing the readings of embedded temperature detectors, given by Mr. Ross and Mr. Towne, is very useful. Efforts have been made by the General Electric Company to reduce the temperature differential between copper and embedded detector by packing the space between the rounded corners of the armature bars and the detector with asbestos putty, which tends to reduce the cooling effect of the ventilating gas on the edges of the detector. While this practice has reduced the temperature differential somewhat, the detectors still read appreciably below the theoretical values for an ideal detector having no heat loss. The development of a shielded type of detector which would read close to the theoretical temperature, as suggested by the discussors, would be a significant accomplishment.

The statement in the paper that curve 4 of Figure 11 might be used as a guide to determine the capabilities of generators at elevated gas pressures was not meant to be taken, as Mr. Ross and Mr. Towne have assumed, without some qualification; the statement presupposed a consideration of the other data given in the paper, particularly Figures 12 and 17, which show the variation in the calculated capabilities of different generators as determined for constant observed armature and field-temperature rises. It is evident from such consideration that curve 4, Figure 11, would be too conservative for some generators and not conservative enough for others. However, for large generators of modern design, this curve doubtless may be considered as fairly representative.

The points regarding cooler performance at elevated gas pressures, and the difficulty of obtaining constant cold gas temperatures at elevated pressures, are most pertinent. The author is gratified to find Mr. Ross and Mr. Towne in general agreement with the major conclusions of the paper and appreciates their generous estimate of the paper's value.

Mr. Fechheimer's discussion has covered several interesting phases of the problem of generator loading at elevated gas pressures. The increased explosion pressures at 25 or 30 pounds per square inch operating pressure can be protected against by a slight increase in the thickness of the generator wrapper plate, which does not increase the generator cost significantly. However, it should also be considered that the possibility of an explosion becomes increasingly remote as the hydrogen pressure is increased, due to the fact that the resultant increase in hydrogen

leakage maintains the hydrogen purity at a higher value.

It is quite possible to design a generator in which the output at elevated gas pressures would be limited by the rotor heating rather than by the armature heating. This would involve, however, operation at armature temperatures considerably below those for which generators are normally designed, which would be uneconomical. The reasons why the heating of the armature rather than of the field winding must limit the load at elevated gas pressures, for the generator used for the example, are given in the paper.

The references cited by Mr. Fechheimer dealing with temperature differences from copper to embedded detector are most pertinent. The article by Wilhelm Peters[3] gives a method for calculating this temperature difference which is more accurate than the method used by the present author in obtaining curve 3, Figure 8, and curve 2, Figure 9, in that it takes into account the difference in thermal conductivities of the armature insulation in the directions along and across the insulation layers, whereas the method used by the author based on H. Lundkvist's article[4] does not. Had Peters' method been used instead of the latter method, the above theoretical curves of temperature difference between copper and an ideal detector would have been appreciably closer to the curves of estimated and measured temperature difference between copper and conventional detector, given in Figures 8 and 9.

To answer Mr. Fechheimer's question on the location of the surface of division of radial heat flow in the rotor tooth, the construction of the rotor for the generator used in the example made it convenient to locate this surface at the bottom of the tooth ventilating duct. The justification for this location is the fact that the tests checked the calculations closely. For rotors having subslots only, the tooth ducts being omitted, the location of this surface will vary throughout the length of the rotor, as was shown in a discussion by the author of the paper by C. E. Peck.[5] However, Mr. Peck states that for rotors of such design little error is introduced in the final result by assuming the surface of division at the midpoint of the radial tooth height and taking a weighted means of the calculated winding temperatures on either side of the surface.

The presence of obstructions or sharp turns in the ventilation circuit of a generator has a significant influence on the heat transfer rate. This was demonstrated by G. E. Luke in his two papers[6,7] on surface heat transfer which showed the effect of change in air path in ducts and of the duct entrance conditions on the heat transfer. Also, R. Richter[8] evaluates an "eddy factor" for duct entrance. In the author's paper these elements of uncertainty were eliminated for the stator ducts through the use of experimentally derived data on heat transfer in ducts in air, corrected for hydrogen by the use of the device described by D. S. Snell, R. H. Norris, and Mrs. B. O. Buckland.[9] For the rotor ducts, their large length-to-diameter ratio made the use of data on straight smooth ducts seem permissible.

The data given by Mr. Fechheimer on duct discharge coefficients and gas flow for a turbine generator rotor are most interesting, and agree substantially with those obtained by the author and associates from similar tests on stationary models, and from the analysis made for the determination of the rotor duct velocities for use in calculating the duct surface heat transfer coefficients. Also, large-scale ventilation tests, using actual generator rotors, were made to confirm the analysis.

Mr. de Koning has suggested the need for an automatic device for determining the permissible loads at elevated gas pressures. The author believes, however, that if accurate data on the temperature difference between armature copper and embedded detector are made available, it should be possible to determine the permissible loads at elevated gas pressures quite simply, from tests at different hydrogen pressures, through plotting the test data as shown in Figures 7 and 15 of the paper.

Mr. de Koning questions whether, in view of the increased complications attendant on operation at elevated gas pressures, some method of cooling other than with hydrogen might not be more advantageous. He has himself proposed vaporization cooling[10] as one possible alternative; while Carl J. Fechheimer has proposed liquid cooling[11] as another. Both these alternatives undoubtedly have merit, but also introduce many complications which, for the present at least, make hydrogen cooling seem simple by comparison.

The increased explosion pressures at 25 or 30 pounds per square inch operating pressure, which Mr. de Koning has mentioned, were also mentioned by Mr. Fechheimer. The dimensions of the generator are determined primarily by its electrical characteristics, and the frame construction must be strong enough to support the stator core and the rotor, and must also be gas-tight. Fulfillment of these conditions as a rule automatically makes the frame strong enough to withstand safely the force of an explosion of the most explosive hydrogen-air mixture. Increasing the hydrogen pressure also increases the gas leakage; hence, it is more necessary than ever to provide adequate ventilation for all areas into which hydrogen leakage could conceivably occur.

Mr. Porter's discussion of the experience of the American Gas and Electric Company in the operation of their hydrogen-cooled generators and synchronous condensers at elevated gas pressures is of much interest and value. His company has pioneered both in the use of hydrogen-cooled equipment and in the utilization of elevated gas pressures, and many of the test data given in the paper were obtained on generators of this company's system.

Mr. Porter has questioned the author's use of an increasing cold gas temperature with increasing gas pressure in determining the capability of a generator at elevated pressures. This follows, however, from the assumption of a temperature of 95 degrees Fahrenheit for the cooling water, which is the temperature for which most coolers now are being designed, due to the increased use of condensate for cooling. With this temperature for the cooling water it is not practical to build coolers that will maintain a cold gas temperature of 40 degrees centigrade at elevated pressures; this point was also made in the discussion of Mr. Ross and Mr. Towne. However, for coolers designed for 90-degree Fahrenheit cooling water, as are the coolers for the generators mentioned by Mr. Porter, it is usually possible to maintain constant cold gas temperature with increasing gas pressure through an increase in the flow of cooling water. In this case, curve 3 instead of curve 4 in Figure 11 of the paper should be used as a basis of rating.

The author did not intend to suggest, as Mr. Porter has assumed, that constant total temperatures should be made the basis of operation at elevated gas pressures, but rather that the capability at elevated pressures be determined as the load giving the same total temperatures as are obtained at 1/2 pound per square inch gauge hydrogen pressure. To obtain the same total winding temperatures at increased output, as are obtained at rated load at a pressure of 1/2 pound per square inch gauge with a cold gas temperature of 40 degrees centigrade, either the hydrogen pressure may be increased or the cold gas temperature reduced. In either case, such operation must be regarded as an abnormal condition resulting in less favorable operating characteristics than are obtained at nameplate rating and causing increased temperature gradients in the winding insulation which may tend to reduce the life expectancy of the generator.

The 43,780-kva 1,800-rpm generator on which Mr. Porter has presented data from tests at elevated gas pressures is Generator Number 3 in Table I and Figure 17 of the paper. The gains in output for this generator at elevated gas pressures, as calculated by Mr. Porter on the basis of constant rotor heating, check the values given in the paper. The capability of this generator at elevated pressures on the basis of constant armature heating was not calculated in the paper, as the test data available to the author was not considered reliable. The 110,000-kva generator mentioned by Mr. Porter was a duplicate of Generator Number 8 in Table I and Figures 12 and 17 of the paper; however, the capability of this generator at 15 pounds per square inch gauge pressure, as calculated in the paper for constant armature and rotor heating, is considerably less than as calculated by Mr. Porter. We believe this discrepancy may be due to the fact that the test data from which Mr. Porter made his calculations were less complete than those available on Generator Number 8; also, the rotor heating data may be less accurate. Experience indicates that an accurate estimate of the capability of a generator at elevated gas pressures from tests requires that at least three or four test points at each pressure be obtained, and that the test data be plotted as illustrated in Figures 7 and 15 of the paper.

Mr. Porter's data on the capabilities of the 18,750-kva synchronous condenser at various gas pressures are interesting. His statement that the field temperature rise is the limiting factor is correct in this instance and applies in general to synchronous condensers.

The reason for this is that the field temperature rise is usually close to the guaranteed value, whereas the armature temperature rise is far below that value on machines designed for zero power-factor operation. If it is assumed that constant cold gas temperature can be maintained for a synchronous machine at elevated hydrogen pressures, so that its capability may be based on constant temperature rises of the windings rather than on constant total temperatures, reference to Figure 11 of the

paper shows that for the 83,000-kw generator at a pressure of 15 pounds per square inch gauge, the output for constant observed temperature rise of the armature winding would be 1.3 per unit kilovolt-amperes, for constant temperature rise of the field winding would be 1.28 per unit kilovolt-amperes, while the output based on constant temperature rise of the armature copper would be only 1.18 per unit kilovolt-amperes. Hence, although on the basis of constant observed temperature rises the field winding of this generator is the limiting feature, on the basis of constant temperature rise of the winding copper the armature is the limiting feature. It is probable that the same would be true for a synchronous condenser with a high armature copper loss where the observed temperature rise approached the guaranteed value.

We agree with Mr. Porter that prompt steps should be taken by the manufacturers to clarify their position relative to the permissible loading at elevated gas pressures. However, until the necessary studies can be made, the author believes that curve 4 in Figure 11 of the paper may be used as an approximate guide, using Figures 12 and 17 in conjunction with the several curves of Figure 11 to indicate the extent to which curve 4 of the latter figure should be corrected for a given generator.

Control of Large D-C Motors Supplied from Ignitron Rectifiers

O. W. LIVINGSTON
FELLOW AIEE

THE purpose of this paper is to explain the basic control methods that have been used in the control of large d-c motors supplied from ignitron rectifiers. Companion papers[1,2] describe the application requirements of this class of equipment, the functioning of the rectifier, and details of a specific application.

To successfully meet the requirements of most applications, a control must be able to start the motor and accelerate it to the desired speed either in the armature or field weakening range without distress or overload to the motor or connected load, to maintain the required speed within acceptable limits in spite of disturbing factors such as supply voltage or load torque fluctuations, and to decelerate or stop the motor without excessive overload or stress on the load. It is well known that a phase-controlled rectifier can be used as an adjustable voltage supply for either the armature or the field of a d-c shunt motor. A companion paper describes a phase controlled ignitron rectifier suitable for this service together with the method of affecting the phase shift. This equipment requires the application of current to the d-c windings of the phase shifting circuit to increase the average output voltage of the rectifier. To obtain full output voltage approximately 200 watts would be required of a typical equipment and the use of series resistance to improve the speed of response might bring the total power required up to 800 or 1,000 watts.

"Open Loop" Armature Control

Perhaps the simplest form of armature control for such a rectifier is shown in Figure 1. In this very simple circuit, a definite voltage derived either through closing of jog relay contacts *JR* or the run relay contacts *RR* is applied to the d-c coil of the phase shift circuit which causes a definite voltage to be impressed across the armature. The run potentiometer, might well be a motor driven device with suitable interlocks so that the run relay contacts may only be closed in the down position, and with an operating speed so adjusted to prevent overloading of the large motor or rectifier during acceleration. This type of system frequently referred to as an "open loop" system would not be particularly suitable for a number of reasons. Variation in supply voltage or variations in motor torque particularly in the low-voltage low-current range will be reflected in the rectifier output voltage and may cause undesirable fluctuations of the motor speed. In addition, variation in temperature, either due to ambient or self heating in the phase shifting circuit may cause uncompensated variations in the output.

Basic Closed Loop System[3]

To circumvent these difficulties a "closed loop" or negative feed-back system in which all or part of the output is compared with a reference or input and their difference, commonly called the error, is used to bring them into closer accord. Figure 2 shows a very simple system of this type showing the reference D, the actual motor voltage feed-back θ, and the error or difference ϵ. In normal operation D exceeds θ by only a small value of ϵ causing the current flow in the direction shown. If some disturbance, such as a line voltage drop causes θ to momentarily decrease 10 per cent, the value of ϵ will momentarily increase many fold which causes an increase in the control current in the phase shift circuit which tends to restore the output θ very close to its original value. However, since it has been necessary to increase ϵ slightly to take care of the increase phase advance necessitated by the low supply voltage the output voltage, θ will not be exactly restored to its original value. The larger D and θ with respect to ϵ required for full output, the smaller will be this percentage error. From this standpoint the higher the ratio of θ/ϵ or more precisely $\Delta\theta/\Delta\epsilon$ the less sustained output error will be experienced. This ratio $\Delta\theta/\Delta\epsilon$ is frequently referred to as the loop gain, just as though the phase-shift circuit and rectifier could be considered as an amplifier. It is evident that the higher this loop gain, the less the system output will be affected by disturbances. This elementary explanation can be supplemented with a mathematical analysis which shows that if the effect of a given disturbance on an unregulated system is known, the effect of the same disturbance on a regulated system with loop gain of K will be reduced by the factor $1/(1+K)$.

This desirability of high loop gain to minimize the effect of system disturbances makes the simple "closed loop" circuit of Figure 2 impractical, due to the large amounts of power required from the reference supply. To illustrate this let us assume that for full output 25 volts and 8 amperes or 200 watts are required by the phase shifting circuit. Let us further assume that the full output voltage is 500 volts supplied to the motor and this entire voltage is fed back to be compared with a reference which then must be 525 volts (500+25). Assuming that the output voltage is essentially proportional to the voltage applied to the phase shift circuit, the loop gain K may be shown to be

$$K = \Delta\theta/\Delta\epsilon = 500 \text{ volts}/25 \text{ volts} = 20$$

This value of loop gain, which is by no

Paper 50-32, recommended by the AIEE Electronic Power Converter Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January–30February 3, 1950. Manuscript submitted November 2, 1949; made available for printing November 30, 1949.

O. W. Livingston is with the General Electric Company, Schenectady, N.Y.

Figure 1 (left). Simple motor control without feedback

Figure 3 (right). Motor control with feedback and error amplifier

means excessive for high performance, requires a reference power supply of

525 volts × 8 amperes = 4,200 watts

Further consideration will show that for any loop gain K the wattage required from the reference supply is equal to the wattage taken by the input to the phase shift circuit multiplied by $(K+1)$. The actual wattage required will exceed even these figures because of the additional loss in the speed adjusting potentiometer which must be kept to a low ohmic value since any resistance it adds to the phase shifting circuit cuts down the loop gain. In the example illustrated, if the total resistance of the speed control and jog potentiometers are 12.5 ohms this will result in an effective resistance of $3^1/_8$ ohms added to the phase shifting circuit at the half speed setting. Since this equals the internal resistance of the phase shifting winding even this low value of resistance reduces the loop gain by one half to the rather low figure of 10. Even assuming such a low gain (and a variation in gain of two to one) is acceptable this results in a further demand on the reference power supply:

$$E^2/R = (550)^2/12.5 = 24{,}200 \text{ watts}$$

This gives a total demand of 28.4 kw on the reference supply which is rapidly assuming the proportions of the main unit and clearly impracticable.

The obvious solution to this situation is to insert an amplifier of some form ahead of the phase shift circuit to give a control system as shown in Figure 3. An amplifier would reduce the power requirements of the reference supply and control potentiometers in direct proportion to the power gain of the amplifier. Thus a gain of 1,000 or more in this amplifier, which is readily obtained, would require 30 watts or less from the reference standard for the same loop gain.

Amplidyne Amplifier[4]

Figure 4 shows an elementary circuit of an amplidyne amplifier suitable for such a control system. In this case the difference between the reference and the output voltage is applied to a control field of an amplidyne which is basically a two stage rotating amplifier which has been frequently described in the literature. A 1-kw 1,800-rpm machine operating over the linear portion of its range will have a power gain in the order of 8,000, which is more than enough to make the size of the reference power supply and adjusting potentiometers sufficiently small to be convenient. The low power level required (0.1 watt for 80 per cent voltage) also makes it convenient to add features which will be described later.

Electronic Amplifier[5]

Figure 5 shows a simple electronic amplifier for the control system being considered. It may be considered as two amplifiers in series, a high vacuum tube amplifier followed by a small phase controlled rectifier using hot cathode thyratron tubes. The error signal is impressed on the grid of the high vacuum tube *VT1* and the anode current is used to saturate the d-c winding of a small phase shifting saturable reactor. The phase shifting network in turn controls the output of the thyratrons *VT2* and *VT3* which are used in the phase controlled rectifier.

In such a system a change of about 2 volts on the grid of input tube is sufficient to control the output of the phase controlled rectifier from no load to full load which may be 1 kw or more depending upon the size of the thyratrons and the anode transformer. In this system if the full motor voltage of 500 were fed back as shown the resultant loop gain would be about 250

$$K = \Delta\theta/\Delta_4 = 500 \text{ volts}/2 \text{ volts} = 250$$

During the normal controlling range the grid current of a vacuum tube such as *VT1* is at least as low as 10^{-7} amperes and generally in the order of 10^{-9} amperes. During any period when the grid might be positive due to transient conditions the grid current that might flow may be limited by a grid resistor as shown. Thus the power input becomes so small and difficult to measure that the power required from the voltage reference source is practically limited by the adjusting potentiometers and that drawn by the anode of the amplifier tube which may for convenience use the same source.

It is interesting to note that such an amplifier requires a definite input voltage change for full output change. The amplidyne described previously requires only a definite power input and within reasonable limits by suitable change in the control field may be designed for full output for almost any input voltage. Thus the actual magnitude of D and θ determine the loop gain in the case of the simple electronic circuit, but not in the case of the amplidyne amplifier where the field winding may be controlled to give a required loop gain. Thus with the electronic amplifier shown, if the value of θ is cut down by a potentiometer across the output so that a more convenient reference in the order of 100 volts may be used, the loop gain will be cut down to about 50. The gain may be further lowered in the same manner if desired, or other simple circuit changes such as the insertion of a cathode resistor or input potentiometer may be employed. On the other hand, if it is desirable to increase the loop

Figure 5 (left). Electronic error amplifier

Figure 7 (right). Current limit added to electronic amplifier motor

gain it is possible to add additional vacuum-tube amplifier stages to obtain almost any gain necessary.

Amplistat[4]

Figure 6 shows an elementary circuit diagram of a magnetic amplifier of the self-saturating type frequently called an Amplistat, used in our control system in the same manner as either the amplidyne or electronic amplifier. It is possible within certain limits to consider this Amplistat a controlled rectifier similar to the output stage of the preceding electronic amplifier. In this case however, uncontrolled rectifier elements of the dry-disk type are used and two output windings of a saturable reactor are connected in series with two elements of a simple single-phase supply rectifier circuit of four elements known variously as "bridge" or "diametric double way." In normal operation the saturable reactor presents a high impedance for part of each half cycle resulting in almost zero voltage output for a portion of the time. Then the reactor becomes saturated and presents little impedance so that almost full output for the remainder of the half cycle is obtained. The point in the cycle when the reactor passes from an unsaturated to a saturated condition is controlled by the net magnetomotive force in the d-c windings. In this case three d-c windings are used. The speed reference voltage is applied to one winding to produce the reference magnetomotive force D, the output voltage to another winding to produce the opposing feed-back magnetomotive force θ, and the third winding is excited from a constant source to produce a bias magnetomotive force B, which merely sets the proper operating point. This differs from the two preceding circuits in that the basic subtraction of reference and feedback to produce the error signal is accomplished by subtracting magnetomotive forces. This has the advantage of isolating the control circuit from the output. It would appear superficially that this subtraction of magnetomotive forces could have been employed with the amplidyne as indeed it can for low loop gains. However we find that assuming the same space is available for the control windings the power dissipated in I^2R losses where magnetic subtraction is used is increased by the factor

$$2(K^2+(K+1)^2)\times\text{normal power}$$

Thus for a K (loop gain) of 20, the losses in the control windings would be 1,682 times as great as when electrical subtraction were employed. In the case of an amplidyne requiring an input of 0.1 watt on a single winding this would result in a copper loss of 168.2 watts, which would normally be excessive for a 1-kw output machine. In the case of the Amplistat, however, much higher power gains in the vicinity of 2.5×10^6 are readily attained which then requires an input power of only 4×10^{-5} watts for electrical subtraction for a 1-kw output. If magnetic subtraction is used with a loop gain of 20, this will result in a copper loss of about 6.75 watts which is not excessive for a saturable reactor having a size somewhat larger than 1 kva.

Comparison of the Three Methods

It is difficult to show that any one of these systems is to be preferred for all control problems of this type. Each of the systems have certain features which may make it most desirable for a given application and each of them have been successfully applied in actual installations. However we will try to compare the technical functions to illustrate some of the reasons for proper selection.

Input Considerations

At the present time the vacuum tube amplifier probably requires the lowest power input and gives the highest power gain per stage. This, however, is not the complete story since this type of amplifier requires a definite voltage change on the

Figure 6 (left). Amplistat used as error amplifier

Figure 8 (right). Motor control using Amplistat

input grid for full output and this voltage change rather than the almost infinitesimal power, determines the design of the input circuit. Both the amplidyne and the amplistat on the other hand require only a given power change on the input, and it is possible to wind the excitation coils to take this power either at high-voltage low current or low voltage high current. Stated in communication terms, it may be said that either the amplidyne or Amplistat input coils may be wound to "match the impedance" of the driving source so that full advantage of their power gain may be utilized. On the other hand a vacuum tube amplifier operated from an error signal source capable of supplying considerable current but very little voltage change is incapable of taking advantage of the current supplying ability of the input. Under these conditions it gives no more output than if the input circuit were only capable of supplying microamperes. Thus the extremely high power gain of the tube amplifier is realized only with high impedance input circuits, such as from photoelectric tubes, but it is incapable of using with a similar efficiency the possible output of a millivolt shunt. The magnetic input to both the amplidyne and the Amplistat on the other hand can not only be designed to use the power available from low voltage input sources, but they have the property of electrically isolating the input from the output circuits which is not possible in a simple d-c electronic amplifier. They also permit, under certain conditions, the addition or subtraction of several electrical signals still maintaining electrical isolation.

Amplification and Speed of Response

These two characteristics are treated together since they are frequently interdependent.

In the d-c high vacuum amplifier such as we are considering, the voltage gain may be built up if necessary by successive stages with resultant control with smaller and smaller input, until the input reaches the level of random noise or tube characteristic drift. The time delay in such amplifiers are so small that they are generally of no consequence in most industrial power applications. The small saturable reactor used for phase control of the thyratron tubes in Figure 5 has a several cycles time constant which normally is of no consequence in most industrial controls. However, other methods of phase control may be used which have no time delay.

Both the amplidyne and the Amplistat

Figure 9. Motor control using electronic amplifier

have time delays due to the change of flux energy stored in the magnetic circuits in passing from one output condition to another. The "time constants" introduced by this are frequently reduced by such methods as adding series resistance to the signal coil circuits. Within certain limits the time constant of a single delay circuit is inversely proportional to the losses in the circuit. Thus if we add a resistor in series with the input winding of an amplidyne or Amplistat equal to the coil resistance, the power required to get the same output is doubled, but the time constant is reduced to one half. Thus, it is necessary to consider the time delays in both amplidyne and Amplistat control and many cases cut down the maximum power gain in order to get fast enough response. It is not uncommon to use two or more stages of amplistats to obtain both high gain and high speed. It is less common to employ two amplidynes to get high gain and speed although in a few cases this has been done.

Nature of Output

The output of the amplidyne may be either positive or negative in voltage depending upon the field excitation, and either positive or negative current may flow depending upon the load. This is very desirable in certain classes of operation where operation in all four quadrants of voltage and current are required.

The controlled rectifier used in the electronic system can basically operate with current only in one direction, but may have not only a positive voltage output but also a negative voltage if the load has the ability to furnish power with a positive current flow. This is another way of saying that a simple controlled rectifier may operate as an inverter with reversed d-c potential and direction of power flow but current flow in the same direction. Thus a simple controlled rectifier normally operates in only two quadrants; the positive voltage positive current quadrant, and the negative voltage positive current quadrant. Of course it is possible to arrange two opposing controlled rectifiers having opposite current directions to a common load but this requires additional equipment.

The simple amplistat is a somewhat restricted controlled rectifier in that it only works in the positive-voltage positive-current quadrant. It cannot be used to operate in the negative voltage, positive current, or invert quadrant. This property makes it difficult to use two reversely connected Amplistats on a common load without appreciable power loss.

Additional Functions

So far we have considered only the basic voltage regulator circuit. For successful control of d-c motors we must consider additional functions such as speed control, acceleration, deceleration current limit, and field weakening.

Speed Control and Voltage Drop Compensation

So far we have indicated the feed-back voltage simply taken from the ignitron rectifier output. While in some cases a constant armature voltage insures a sufficiently constant motor speed this is not always the case. When the load torque varies from zero to full value the motor speed for constant armature voltage may drop 5 per cent or 10 per cent of basic speed, depending upon the armature resistance, armature reaction effect, and series stabilizing fields if used. One way to overcome this difficulty is to couple a small d-c tachometer generator to the motor shaft and feed this signal back instead of the armature voltage signal. Then the closed loop system will try to maintain this tachometer voltage or the speed constant under varying load torque conditions.

While this is generally a very satisfactory method, there are some cases where the addition of the tachometer generator might be objectionable. In

this case it is possible to compensate for the motor speed drop by increasing the terminal voltage as a function of load drawn by the motor. One convenient way to do this is to insert a current transformer in the ignitron rectifier circuit, rectify the output and feed a small resistor load. The voltage across this resistor will then be proportional to the load current and an adjustable portion of it is added to the reference voltage. This voltage drop compensation, if properly adjusted, has the effect of raising the terminal voltage as the load torque is increased so that the motor continues to run at essentially the same speed as at no load.

Acceleration

Some method must be used to prevent applying full voltage to a large d-c motor at standstill or excessive currents will damage both the motor and the rectifier. One very simple method is time acceleration. The run potentiometers of Figures 4, 5, and 6 may be motor driven with suitable interlocks to prevent closing the run relay unless the run potentiometer has been returned to the bottom position. The speed of the motor-driven potentiometer is then made slow enough to permit the main motors to accelerate without damage to any of the equipment.

On those applications where varying load conditions prevail and maximum safe speeds of acceleration are desirable the control may be designed to accelerate the motor at a definite current limit. While a current limit "take over" function can be added to any of the three systems described earlier, Figure 7 shows the current limit function added to the front end of the electronic control shown in Figure 5. As in the case of voltage drop compensation, a signal is derived from a current transformer in the rectifier supply, rectified and impressed across a resistor giving us a voltage θ_1 proportional to rectifier or motor current. As long as the current signal is small compared to the permissible current limit signal D_1 the cathode of the diode *VT4* is positive with respect to its anode which is connected to the grid of *VT1* which is two or three volts negative with respect to the bottom bus. Under these conditions the diode *VT4* is like an open switch and the speed regulating function is undisturbed. However as the load current becomes greater θ_1 increases until it exceeds D_1 and soon the cathode of *VT4* falls below its anode. This causes a current to flow through the diode and through the rather large grid resistor in *VT1* circuit. This "take over" causes the grid potential of *VT1* to become more negative which then tends to decrease the current in *VT1* and ultimately the rectifier voltage in spite of ϵ becoming more positive. We see that under these current limit conditions a new closed-loop system is operative involving a current limit reference D_1, a current feed-back signal θ_1, and a current error ϵ_1.

Even if the run potentiometer were set at the top of its travel, such a circuit would maintain constant current during the acceleration period until the desired speed was obtained. At that point the speed error ϵ would make *VT1* grid more negative and since the current limit circuit cannot make the grid more positive, the speed error would "take back" the control and regulate the speed.

Field Weakening

In some cases where constant horsepower variable speed is required, it is necessary to run motors above basic speed by field weakening. This may be accomplished several ways. One of the simplest methods when a motor-driven potentiometer is available for acceleration is to have the resistance vary only during the first part of the travel. During the remainder of the shaft rotation, the slider travels on a conductive segment and the armature voltage does not change. Keyed to the same shaft is a second potentiometer for control of the field. During that period of travel when the armature voltage is increasing the slider of the field control potentiometer is running on a conductive segment. After the armature voltage ceases to rise the slider of the field potentiometer moves on the resistance section and reduces the field reference voltage. The field may be supplied by an amplidyne, controlled rectifier, or amplistat connected in a closed-loop control similar to that used for the armature circuit. Thus during acceleration to full armature voltage the field is maintained at full value and then is reduced by further shaft travel to the desired degree of weakening.

Figure 10. Motor control using amplidyne amplifier

While this paper has been primarily devoted to an explanation of the basic control methods that have been used with d-c motors supplied from ignitron rectifiers, Figure 8 may be of interest as an example of the class of control equipment being considered. Figure 8 shows the control equipment using an amplistat-type regulator for a printing press drive. The dynamic braking contractor is located in the upper left of the left-hand control, the motor driven rheostat in the center, and the d-c disconnecting switch in the lower left-hand side. No d-c loop contactor is required since the d-c circuit is effectively opened by removing the ignitor excitation for the rectifier. Many of the other relays are used in connection with a rather elaborate safety system which delays the initial start of the press while sufficient warning is given to the press operators to get clear.

The saturable reactor and selenium rectifier associated with the amplistat are situated in the rear of the rectifier cubicle located adjacent to the panel shown. The saturable reactor has the approximate physical size of a 1-kva transformer and the selenium rectifiers approximately that of a 1-kw selenium stack assembly.

This application differs from some others in that a variable number of motors may be run from one rectifier depending upon the number of presses to be run with a given folder. The right-hand panel is basically a motor transfer panel which permits connecting certain of the

press motors to either one or the other of two rectifiers depending upon the press set up for the particular edition.

Figure 9 shows similar equipment using an electronic amplifier. The central panel in the left-hand cubicle contains the high-vacuum tube amplifier with provisions for voltage drop compensation, current limit, and parallel operation of two rectifiers. The panel immediately below contains the thyratrons of a 6-phase controlled rectifier to saturate the phase shifting reactors of the ignitron rectifier. The panel below and slightly to the front of that contains the four thyratrons for the motor field supply.

Figure 10 shows the control panel using an amplidyne-type amplifier for affecting the phase shift of the ignitron rectifier. In this case a single 350-horsepower motor driving a flanging mill is involved.

Summary

From a consideration of the problems of the control of a d-c motor supplied from a phase controlled ignitron rectifier we have tried to show:

1. The closed loop or feed-back system is highly desirable.

2. Such a system requires the use of some form of amplifier between the reference and comparison circuit and the ignitron phase shift system.

3. Three different systems involving the use of amplidynes, electronic amplifiers, and amplistats have been successfully built to serve this function.

4. The choice of the best method for a particular application depends upon the particular requirements of that application.

RECTIFIERS have proved very reliable and successful in supplying d-c power to all types of application: street railway, mining, steel mills, electrochemical, and general industrial. The use of rectifiers for d-c motor control is a natural development due to their ease of control, high speed of response, and use of all static components. The study of economics made for d-c motor drives indicated that 550 volts of direct current gave the best return, and, accordingly, standards have been made at this voltage. A 3-phase double-way (full wave) rectifier will deliver 550 volts of direct current when supplied from a 460-volt 3-phase system. This is a standard distribution voltage and standard transformers are available, thus eliminating the added cost for special transformations.

The purpose of this paper is to give a description of the rectifier circuit, to show how voltage control is accomplished, to show how the "Amplistat" controls and regulates the output voltage, and to describe the physical layout of the rectifier.

The majority of d-c motor applications can be supplied from 150-, 300- or 500-kw power units, and rectifiers have been standardized in these ratings. The 300-kw rectifier is shown in all figures of this paper. The 150-kw size is identical except for tube size, but the 500-kw units are larger and use a larger size tube. The d-c motor drive unit is housed in four standard cubicles of dead front, totally-enclosed type, and each cubicle is assembled in line with the others. The first cubicle contains the low voltage a-c circuit breakers and the current limiting reactor. The second cubicle contains the sealed ignitron tubes, their excitation circuits and cooling system. The control cubicle is the next in line, followed by the cubicle containing the d-c motor switching circuits. The front view of this type of assembly is shown in Figures 5 and 6. A diagram of one complete rectifier equipment of this type is shown in Figure 7. A multiple arrangement of four similar rectifier units is shown by the diagram in Figure 8. Any number of similar combinations can be arranged in this manner to make a complete d-c unit substation.

Rectifier Circuit

The basic elements of a typical electronic d-c motor drive system are shown in the 1-line diagram of Figure 1. This diagram shows two identical rectifier units, an a-c tie circuit breaker and two sets of d-c motor switches. The a-c tie circuit breaker allows the equipment to be operated from either of the two secondary a-c feeders. The d-c motor switches permit selection of different motor and rectifier combinations. This affords a large degree of flexibility and reliability. A complete installation generally consists of one or more pairs of units connected in this manner.

The interrupting rating of the main a-c circuit breaker and the reactance of the current limiting reactor depend upon the maximum fault current capacity of the sealed ignitrons and the available short circuit kilovolt-amperes of the a-c system supply. The rectifiers may draw 10 to 20 times normal load current during a fault. The maximum fault current capacity of three types of sealed ignitrons is shown in Table I.

Table I. Maximum Fault Current Capacity of Three Types of Sealed Ignitrons

Ignitron	Rated Amperes	Maximum Fault Current, Amperes
A	100	3,500
B	200	12,000
C	400	25,000

The available primary 3-phase short-circuit kilovolt-amperes are usually 500,000 kva. The maximum rectifier fault current which can flow depends upon the kilovolt-ampere rating of the feeder transformer. If two 300-kw rectifier units are connected as shown in Figure 1, a current limiting reactor which has a value of 0.0163 ohms per phase will be sufficient to limit the fault current to a safe value. This reactance is obtained when either feeder transformer is assumed to be rated at 750 kva. The interrupting rating of the circuit breaker will be 25,000 amperes with such a transformer. Both the circuit breaker and the reactor will have a continuous current rating of 600 amperes. Rectifiers of ratings other than 300 kw will have corresponding values.

Power losses in the rectifier consist of two types. One is the kilowatt loss due to arc drop in the tubes and the resistance loss in the current limiting reactor. This loss varies with the load current being drawn from the rectifier. The resistance loss in the reactor is so small that it is usually included in the arc-drop value. The other type of loss is the power required by the rectifier excitation system and this is the no-load loss and is constant for all values of load. This is usually 1.7 kw for all ratings of the standard rectifiers. The over-all efficiency of the rectifier unit at full voltage ranges from 92.6 per cent at 25 per cent load to 93.4 per cent at 100 per cent load.

Paper 50-33, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted November 2, 1949; made available for printing November 30, 1949.

M. J. MULHERN and S. N. CRAWFORD are both with the General Electric Company, Schenectady, N. Y.

Figure 1 (left). One-line diagram of typical electronic d-c motor drive system

Figure 3 (above). Rectifier regulation characteristic

The circuit diagram of Figure 2 shows the complete power and excitation circuits for one rectifier unit. The tubes are connected in a 3-phase double-way circuit. At full output the waveform of the direct voltage has a 6-phase ripple. Standard d-c motors are not overheated when operated on a supply voltage with small percentage of ripple, and consequently do not have to be derated.

D-C Voltage Control

Conduction in the sealed ignitron tubes is initiated once during each cycle by the "firing" of the ignitor. The ignitor initiates emission, when it is fired, by establishing a "cathode spot" on the mercury pool. The ignitor is fired by the application of a high-voltage pulse of short duration. The tube will begin carrying current whenever the ignitor fires, if its anode voltage is positive. The conducting period of the tube will be reduced if the ignitor firing is delayed in time for an appreciable part of one-half cycle. The direct voltage output of the rectifier is correspondingly reduced, as shown in Figure 9. The direct voltage is, therefore, proportional to the angle of phase-retard of the ignitor pulse.

The effect of voltage regulation of the rectifier power supply is shown in Figure 3. The curve of E_d shows how the output voltage normally drops as load is increased from zero to full load. This would cause considerable change in motor speeds as load is applied to the motors. It would, therefore, be difficult to control accurately the speed of the motors if the load were being changed. This effect is greatly reduced when the armature voltage is regulated, as indicated by the curve of E_{dr}.

Figure 2. Rectifier circuit diagram

Excitation System

The excitation system consists of the circuits which control the conduction of the ignitron tubes. The principle requirements of a d-c motor drive are that: the armature voltage be continuously adjustable from zero to maximum voltage; that the armature voltage be regulated; and that the time of response in regulating be small compared to the inertia effects in the load.

These requirements are met by the various circuits in the excitation system. These circuits are shown in Figure 2. They may be broken down, for convenience, into four groups of circuits:

1. The ignitor and excitation anode circuits.
2. The variable phase-shifting network.
3. The fixed phase-shifting circuit.
4. The Amplistat and signal circuits.

The ignitor circuit consists of a static

Figure 4. (A, B, and C). Functional diagram and characteristics of excitation system

magnetic firing circuit which provides a high-voltage firing pulse once each cycle for each ignitor. Each circuit is arranged to operate on both half-cycles of input voltage and thus produces two ignitor pulses 180 degrees apart. The excitation anode circuit energizes that element in the ignitron tube and maintains the cathode spot which is established by the ignitor. There are three ignitor firing circuits connected in 3-phase relation. There are also three excitation anode transformers and associated circuit elements connected in 6-phase relationship.

The phase-shifting network shifts the phase of the input voltages to the ignitor and excitation anode circuits. This network provides a constant voltage output over the full-phase shift range so that the performance of the firing circuits does not change. The time of response of this network is less than two cycles at 60 cycles.

The fixed phase-shift transformers are adjusted to bring the ignitor pulses into proper phase relation with their respective tube anode voltages. They consist of three multiple winding transformers which can be connected for fixed shifts of 5 to 355 degrees in ten-degree intervals.

The Amplistat and signal circuits combine and amplify all signals which are to modify the rectifier output voltage. The output of the Amplistat is a control current which varies the actual phase-shift angle in the phase-shifting network.

All of the excitation circuits provide continuous functions, and, therefore, continuous control of the rectifier voltage. This is illustrated by the functional diagram of Figure 4(B).

The Amplistat Circuit

This circuit is made up of a magnetic amplifier and its associated control signal circuits. The Amplistat circuit controls the amount of phase shift of the excitation voltages. The basic element is the magnetic amplifier reactor, a completely static device. The amplifier circuit has extremely high gain and over-all characteristics similar to an electronic amplifier or an amplidyne unit. The basic characteristics of these three types of amplifier are described in a companion paper. The Amplistat has been selected for this type of rectifier equipment because it has physical and electrical characteristics closely matching the firing-circuit and phase-shifting circuit components. It has no moving parts and no filament life. It is thus possible to build into all portions of the excitation system the same degree of reliability, freedom from frequent component replacement, and freedom from wear.

The Amplistat is a signal mixing device as well as an amplifier. The several con-

Figure 5. Front view of rectifier and control equipment for electronic d-c motor drive installation

Figure 6. Front view of equipment of Figure 5 with doors open to show air circuit breaker, space for reactor, ignitron tubes, automatic control devices, and motor selector switches

Figure 7. Arrangement of basic electronic d-c motor drive equipment

trol windings of the reactor all have ample insulation permitting connections to other circuits without the need for additional insulation. This results in greater simplicity and lower cost in the design of the control circuits by reducing the number of insulation levels required.

The characteristic of the Amplistat is shown in Figure 4(C). It has essentially a negative signal characteristic, that is, most of the control range is covered in the region of negative signal input.

The Amplistat differs from other amplifiers in that the actual input signal is ampere-turns (magnetomotive force) rather than voltage or current. This presents no practical problem because the signals are measured in terms of current in each circuit. When only one signal is applied to the Amplistat, its output is proportional to the amplitude of that signal. When more than one signal is applied, the Amplistat output is proportional to the algebraic sum of all of the signals. This sum is called the net signal. The output of the Amplistat is, therefore, determined by the instantaneous values of all the signals applied to it. In the d-c motor drive equipment, the minimum number of signals is three, as indicated in Figure 4(C). These signals are bias, control, and feed-back.

The bias signal calibrates the Amplistat, in effect, so that the polarities and amplitudes of the other signals will vary over the useful range of control. The control signal is a manually adjusted (or automatically controlled) current which indicates to the system the value of direct voltage to be held. The characteristic curve in Figure 4(B) shows that the output voltage of the rectifier is directly proportional to the magnitude of this signal current.

Voltage regulation also is a requirement of the system and the closed loop method is employed. The regulating loop is shown in Figure 4(A), and includes the Amplistat, phase-shifting network, firing circuits, and the rectifier. The loop is closed by the feed-back signal which is proportional to the instantaneous value of direct voltage. This signal is polarized in opposition to the control signal and their difference is called the error signal. The error signal is amplified by the Amplistat, which ultimately adjusts the direct voltage, and thus the result is a continuous regulating function. The net signal and the error signal are not the same, since the net signal is an absolute value and the error signal is not.

When the control signal is adjusted to a new value, the output voltage of the rectifier shifts to a new value. The feed-back signal also changes to a new value and the regulating function continues at the new level. The action is smooth and rapid because of the high gain of the Amplistat circuit and the short time of response of the phase-shifting network.

The effects of line-voltage changes on the regulating system are minimized by using regulating transformers to energize both the Amplistat circuit and the control circuits.

Assembly

The cubicles are designed to match and line up with the a-c switchgear cubicle and in all cases are 60 inches deep and 30 inches wide for the 150- and 300-kw rating and will be 60 inches wide for the 500-kw rating. The assembly is completely metal-enclosed, dead front, with doors both front and rear providing access to the ignitron tubes and excitation system. The sealed ignitron tubes are mounted in the front section on suitable insulators, and power connections are taken through the front panel to the rear, where factory assembled cables are brought out to the a-c and d-c connections respectively. The front of the equipment also mounts the cooling system for the ignitrons.

Figure 8 (below). Group arrangement of basic electronic d-c motor drives

Figure 9 (right). Rectifier voltage control

The cubicle assemblies are shown in Figures 5 and 6.

The rear door mounts the Amplistat which controls the d-c output of the rectifier by integrating signals from the magnetic control section. The Amplistat and its component parts employ all the available space on the rear door. The excitation systems are mounted in the interior of the equipment and all necessary components for two ignitors are mounted on one panel, therefore there are three excitation panels. The components for the excitation circuits are nested in together so as to use the least amount of space, but all component leads are brought to terminal boards which are readily accessible for testing. Should an emergency arise, components may be temporarily connected directly to these terminal boards. The operator may make permanent replacement at his convenience.

It is necessary to provide cooling water to remove the arc loss in the sealed ignitrons. As the load varies, the arc loss will vary and consequently the amount of cooling water required will vary. In order to protect the rectifier from loss of cooling water, a water flow relay is included in the outgoing water line which will de-energize the rectifier if sufficient water flow is not available. Overtemperature protection is provided by the use of a thermostat which is located in the outgoing water line so that if the water available is not sufficient for the load being carried but is sufficient for the setting of the water flow relay, the rise in temperature will also de-energize the rectifier. Electrolytic targets are provided at various points in the water system to protect the piping materials from electrolytic erosion. These are of sufficient lengths so that inspection at six months will enable the operator to know what future inspections are necessary. Valves are provided to isolate the rectifier from the water system and drain cocks and pet cocks are provided so that, in the event a tube is to be changed, the water system may be drained before the tube unions are opened. As most installations experience humid weather and usually the cooling water is fairly cool, drip pans are provided which collect the condensate from each tube and are of sufficient size so that natural evaporation will take care of the water collected.

Summary

This paper has endeavored to show a functional description of an adjustable voltage rectifier equipment which delivers moderate power and is suitable for the control of one or more d-c motors. These rectifiers incorporate high gain amplifier and excitation circuits which have a high degree of reliability and freedom from frequent maintenance. A well-regulated output voltage is obtained by the use of the Amplistat circuit. The output voltage may be continuously adjusted in response to several system conditions as required. The assembly is made compact and economical by full utilization of the cubicle space. These features make possible a packaged, unit type of rectifier equipment which meets all the service requirements of industrial applications requiring regulated variable voltage source.

Application of Electronic Motor Drives to Printing Presses

J. A. JOHNSON
NONMEMBER AIEE

E. M. STACEY
MEMBER AIEE

Synopsis: At least 50 years have passed since rotary web printing presses reached, essentially, their present form. As innumerable refinements gradually improved the quality of the product and increased speed of the presses, corresponding advances were made in electric motor drives. Press drives, as a result, are highly refined, specialized equipments designed to do a definite job. Application problems will be discussed, together with a comparison between conventional and electronic solutions.

The Printing Press

A modern high-speed metropolitan newspaper press is shown in Figure 1. Figure 2 shows schematically how a continuous web of paper is fed to each unit, is printed on both sides, and passes to the folder. It is delivered from the folder as a complete newspaper.

All rotational energy is imparted to the heavy newsprint feed rolls through the paper webs. With paper speeds of 1,500 feet per minute, or more, acceleration rates and torque peaks from the electric drive must be severely limited.

In preparing a press for printing, the paper webs are first threaded through at about 35 feet per minute. The electric drive must, therefore, provide a continuous threading speed of about $2^1/_2$ per cent of full speed.

Next, type plates are clamped to the plate cylinders. This requires jogging the press by fractions of an inch in order to position the slots into which the plates fit. The drive must provide crisp, accurate inching action for this service.

The press is then accelerated smoothly to approximately 20 per cent speed for registering the webs and other adjustments, after which it is gradually accelerated to its production speed. Production is normally at from 75 per cent to 100 per cent full speed. Thus, the drive must provide smooth acceleration and deceleration over a 5-to-1 speed range, and, preferably, high efficiency over the production range.

In event of a web break, or other mishap, the press must be stopped in about eight seconds from full speed. The electric drive normally furnishes a large part of the required braking torque.

Finally, and perhaps most important of all, a press drive must be reliable. Editions should not be late, and must not be missed.

Conventional Press Drive

A very serviceable answer to the press drive problem has been given in the past, and is still being given in many plants, by the a-c double-motor drive. The operating speed range is provided by a wound rotor main motor with secondary resistance control down to 20 per cent speed. A separate small threading motor is used

Figure 3. Electronic drive motor arrangement looking upward from reelroom floor

Figure 4. Efficiency and power factor characteristics of electronic press drive

for the jogging and low-speed threading functions.

The wound-rotor motor drive, however, suffers from certain inherent drawbacks. First of all, the extra threading motor, with necessary reduction gearing and over-running clutch, causes undesirable mechanical complications.

Secondly, efficiency of a wound rotor motor drops off directly with speed. This not only wastes energy, but, in large installations, makes necessary expensive provisions for getting rid of the secondary resistor heat. Production speed, counting various slowdowns, seldom averages more than 70 per cent of the full geared speed.

Thirdly, speed regulation gets progressively worse as speed is reduced. To compensate for different loads, as press units are added or subtracted to vary the number of pages in the newspaper, special adjustments must be made to the secondary resistors. Unless these are properly made, a web break may result from excessive acceleration when going from threading speed to minimum operating speed.

Electronic Drive

The electronic printing press drive[1] eliminates these drawbacks. Jogging and threading, as well as high-speed operations, are accomplished by the main motors. These are mounted on the side frame of the press, co-axially with the press shaft, in the simplest possible mechanical arrangement, Figure 3. Overall efficiency of the system stays at a high value over the full production range,

Figure 5. Schematic circuit of electronic drive system

Figure 6. Comparative power losses of electronic drive versus wound rotor drive

Figure 7. View of electronic drive control room of the Los Angeles "Mirror" showing equipment for operation of three presses

Figure 4. Speed and acceleration rate are not materially affected by load changes.

The adjustable voltage rectifier[8] achieves all this by combining the advantages of a-c power distribution with the excellent speed control characteristics of d-c motors. At the same time, a high degree of reliability is maintained by use of dependable, time-proved components arranged in a basically simple system.

Figure 5 shows how 440-volt 3-phase power is rectified to direct current in a 3-phase double-way ignitron rectifier, and fed directly to the armatures of the press drive motors. Voltage is adjustable from zero to 550 volts by means of the closed-loop amplistat regulator acting to phase the tubes ahead or back as a function of reference voltage.

Speeds above motor base speed are obtained by shunt field weakening controlled from the amplidyne regulator. References for the armature and field regulators are taken from a pair of ganged potentiometers driven by a common pilot motor. Press mounted "fast-slow" buttons control the pilot motor. Taper of the potentiometers is such as to give linear and virtually stepless acceleration, from threading speed to full speed, in 35 seconds, as the "fast" button is held down. Deceleration is at the same rate. Any speed above $2^1/_2$ per cent can be held continuously and accurately.

Conventional dynamic braking can be set to give any desired rate of stopping.

As many as nine 40 horsepower motors are mechanically coupled to operate in parallel to drive large press combinations. Compound wound motors are furnished with just enough cumulative series field to provide for load sharing between motors.

A motor is furnished for each press unit, so, as units are added or subtracted, the per cent loading on each of the motors in use remains constant. Thus essentially shunt speed regulation characteristics are obtained regardless of press size.

Economic Considerations

The operational advantages just described can often be justified economically when all factors are considered. Although first cost of a complete electronic press drive is usually slightly higher than a-c wound rotor drive, the savings in power costs, maintenance costs, and installation costs tends to more than make up the difference. These savings vary widely, so only the factors affecting them will be discussed.

Power savings result from the higher efficiency at reduced speeds of electronic drive over wound rotor drive, Figure 6. A press geared for a maximum speed of 50,000 papers per hour will usually average, while running on the main motors, a production speed between 30,000 and 40,000 papers per hour. For a given installation, this difference in efficiency can be determined approximately and factored against total energy requirements and local power rates to find yearly savings. Often, a very material annual saving is indicated.

Electronic drive lends itself particularly well to treatment in the same manner as modern switchgear. Installation costs are reduced to a minimum by virtue of factory assembled and wired cubicles which need only be bolted down and interconnected, Figure 7. Since no major power is dissipated in the control room, special ventilation is not required. A saving of $15,000 on air conditioning equipment alone was estimated by the consulting engineers on a recent large installation.

Electronic drive furnishes, with its direct coupled d-c motors, all the functions formerly requiring a main motor, a threading motor, reduction gearing, an over-running clutch, a mechanically-operated brake, and a chain drive. Reduced maintenance expense can be expected from this simplification.

Note, in the control cubicles, Figure 8, the absence of power contact making or breaking devices such as contactors or power rheostats. The one exception is the

Figure 8. Interior view of cubicles for operating one press

From left to right: feeder circuit breaker and current limiting reactor cubicle, ignitron rectifier cubicle, magnetic control cubicle, and motor selector cubicle

dynamic braking contactor which operates infrequently. Otherwise power is turned on and off by the ignitron tubes which are noted for their reliability and long life.

At the present time large electronic press drive installations are operating in four metropolitan newspaper plants in this country. These total 28 ignitron rectifiers powering motors aggregating over 5,000 horsepower. Equipments for four more publishers, totalling ten rectifiers and approximately 2,000 horsepower in motors, now are in process of manufacture or installation.

A number of electronic drives have been on regular production for over a year now, and have proved exceptionally satisfactory on the score of reliability and general performance.

Conclusions

In conclusion, printing presses are a sound field for application of electronic motor drive. Functionally, electronic drive is superior to any conventional drive. Reliability is equal or superior to that of any other type of drive. Economically electronic drive can be justified in the majority of metropolitan installations, and, as advances continue to be made, will certainly become more and more adaptable to smaller installations. All things considered, electronic drive gives definite promise of being the printing press drive of the future.

Flame Detectors for Domestic Fuel Burner Safety Devices

JUSTIN A. DEUBEL
MEMBER AIEE

THE control of fully automatic domestic fuel burners has brought about diverse problems. Especially is this true where the fuel used is gas or oil, consequently entailing a certain degree of explosive hazard. Generally these burners are of the "on-off" variety under control of a room thermostat.

A typical domestic oil burning system is provided with means of feeding fuel to a combustion chamber and with means for electrically igniting the fuel. The electrical ignition system is usually turned off shortly after the start of each running period after the fuel is well enough lighted to self sustain ignition. The safety combustion control equipment for such a system, exclusive of other features, must be capable of accomplishing the following functions. It must:

1. Prevent starting until after a purge interval, if more than five seconds of unburned fuel, vapor or gas has accumulated in a hot combustion chamber.

2. Shut down to a manual reset safety position within two minutes in the event the fuel fails to ignite on a normal start.

3. Disconnect electric ignition means after fire is satisfactorily ignited.

4. Shut down to a manual reset safety position, or recycle after a safe scavenging period, in the event the fire fails after once having been successfully ignited.

In order to accomplish these functions, a detector must be used to enable the remainder of the control to know if flame is absent or present and to respond accordingly.

On an automatic domestic system burning gas, the safety equipment is less involved, since here intermittent electric ignition is not employed. A gas pilot is allowed to burn continuously. It is assumed that if the pilot is burning it is safe to admit fuel. The safety equipment for this application must permit the admission of fuel on demand for heat from the room thermostat if pilot flame is present, and must prevent admission if pilot flame is absent.

The purpose of this paper is to discuss various ways of detecting flame which are suitable to oil and gas applications. Devices for this purpose may be classified into four classes:

1. Those responding to the temperature of the products of combustion.

2. Those responding to the total radiant energy of the flame.

3. Those responding primarily to the luminous radiation of the flame.

4. Those responding to the electrical conduction of the flame.

The requirements for a flame detector for these applications are that the flame detector responds to actuate a switch as quickly as practicable, to the presence or absence of flame, in order to minimize hazards. The maximum response time actually permissible depends upon application and circuit arrangement but generally for oil the response to presence of flame should not exceed 30 seconds and response to absence of flame should not exceed 15 seconds. If this time can be held to less than five seconds circuit simplifications are possible. For gas the response should not exceed three minutes to either absence or presence of flame.

In order to meet speed requirements in both directions, it is often necessary to make detectors respond to *change* in condition rather than a fixed magnitude of condition. For example, if the detector is made to respond to the secondary property of the flame, temperature, it must operate as a function of the change of temperature. It must close on an increase of temperature of a prescribed amount and open on a decrease in temperature of a prescribed amount. It must not open and close at a fixed temperature as a conventional thermostat would do. In order to obtain these effects slip friction mechanisms are fre-

quently used as will be described here.

Also, flame detector switches must fail safe, or circuit arrangements be made to check the action of the switch so no more than 1-cycle sequence is completed if the switch is not functioning properly. This is often done by a "cold check" arrangement, a discussion of which is beyond the scope of this paper except to say that single-pole double-throw switch action with an over lap in one direction may be required. For simplicity the illustrations here show only single-pole single-throw switch action.

The life of switches for this purpose should be of the order of 100,000 operations. The switch load is usually nominal consisting of only control circuit components of about ten voltamperes.

Class 1. Detectors Responding to the Temperature of the Products of Combustion

By far the highest percentage of domestic oil and gas burner controls use the class one type of detector because of its simplicity and inexpensiveness. Elements of this nature are usually arranged to be mounted in the smoke stack of an oil burning furnace and adjacent to the pilot of a gas burner. They are constructed in several styles and in general use the differential thermal expansion of two dissimilar materials to actuate an electrical switch.

One form of such a device which made its appearance in commercial form about 1936 is shown in Figure 1. It comprises a relatively high-expansion U-shaped channel element of 18 mils thick, stainless steel secured at the open end and a relatively low expansion tube about 8 inches long of 18 mils thick, 42 per cent nickel invar secured to the bottom of the U-shaped element. Upon the application of heat, the legs of the U-shaped element lengthen, pulling the tube with them and providing a resultant motion of about 0.001 of an inch per 20 degrees Fahrenheit temperature change. This motion is coupled to the electrical switch through a "slip friction" transmission and a multiplying lever of approximately 20 to 1. The slip friction transmission consists of two carbon blocks secured to the switch actuator arm and arranged to have sandwiched between them a flexible blade secured to the inexpansive member of the thermal element. When there is a differential expansion of the thermal element, the inert member moves and the switch actuator arm follows due to force transmitted through the "sandwich" until the actuator arm engages either one of two mechanical limit stops.

Further motion of the thermal element results in slipping the flexible blade within the carbon block sandwich. A reversal in the temperature of the thermal element results in immediate reversal of the motion of the switch actuator. With this construction the switch is arranged to operate on temperature difference and is calibrated to close on a rise in temperature of about 25 degrees and open on a fall of temperature of about 75 degrees Fahrenheit. Total travel of the switch arm at the contacts between stops is approximately 0.1 inch. Such a device is suitable for use in locations where the maximum temperatures under continuous duty range from 350 to 1,000 degrees Fahrenheit.

Another form of the first class of detectors which made its first commercial appearance in the early 1920's is shown in Figure 2. Here a bimetal helix approximately 32 mils thick comprised of the same materials as the element described previously is arranged to rotate a shaft on temperature change. Rotation of the shaft is made to actuate a switch through a rotary slip friction transmission. Rotation of the switch arm is made to be approximately five mechanical degrees between stops. This motion corresponds to approximately 70 degrees Fahrenheit change in temperature.

Another form which commercially appeared about 1939 is shown in Figure 3. A group of bimetal elements is arranged to give linear motion. This motion through a slip friction transmission actuates the switch. In this case, motion from the thermal element proper is much greater than that shown in Figure 1 and does not need to be multiplied. The temperature motion relationships are otherwise approximately the same as for the first example. All three of the elements described are commonly built to mount in a smoke stack through a $1^1/_2$-

Figure 3. Temperature sensitive flame detector utilizing linear motion of bimetal "ladder"

Figure 5. Flame detector responsive to total radiation utilizing a diaphragm and ring

Figure 7. Flame detector responsive to total radiation utilizing a compensated bimetal spiral and mercury switch

inch diameter aperture and are from 4 to 8 inches long.

The three detectors just described are those most commonly used on conventional oil burner applications, and it is estimated that one of the three forms appear in 90 per cent of all current domestic installations. All three are reliable and function very satisfactorily although each type has its own proponent. All three, when installed in the stack of a conventionally designed furnace having ultimate stack temperatures of 400-700 degrees Fahrenheit, will respond in less than 30 seconds to the presence of, and in less than 15 seconds to the absence of, flame in the combustion chamber. The time constants of the detectors proper is of the order of 15 seconds. The additional time lag is caused by the furnace characteristics.

Shown in Figure 4 is another interesting form of flame detector used primarily to detect the absence or presence of a gas pilot flame using thermoelectric effect. A type *446* stainless steel and Constantan thermocouple is arranged adjacent to the pilot burner so a portion of the pilot flame impinges upon it. This thermocouple when heated excites a coil of an electromagnet producing about 16 ampere turns of magnetomotive force resulting in sufficient flux through a permalloy magnetic circuit to hold an armature in closed position, and thus keep an electrical switch closed. When the thermocouple is cooled the electromagnet is de-energized and the armature drops, opening the electrical switch.

The greater percentage of detectors of this sort are arranged so that the magnetic circuit must be closed manually but once closed will remain so, as long as the thermocouple temperature exceeds a certain set value. These devices may, however, be built as relays to both open and close circuit under the effect of temperature alone.

The portion of the thermocouple subjected to the pilot flame is cylindrical in shape about 1/4 inch in diameter and about 1 inch long. Normally one-half of this is bathed in the flame. The cold junction is located about $2^1/_2$ inches from the hot junction. Connections from the location of the cold junction to the electromagnet coil may be of copper, usually a copper wire within a copper tube.

The iron circuit may have a mean length of about $2^1/_4$ inches and a cross section of about 1/16 square inch. The temperature difference between the hot and cold junction must be of the nature of 600 degrees Fahrenheit in order to retain the armature in closed circuit position. This form of flame detector which appeared commercially about 1934, has found great favor in the gas field. It is estimated that 70 per cent of the currently installed flame detectors for gas pilots are of this type. This unit fails safe if the conductors fail either open or short circuited. It is both rugged and simple, has few moving parts and has proved to be very reliable. Ambient temperature of 900 degrees Fahrenheit may be tolerated with suitable design. The temperature of the hot junction under these conditions may approach 1,400 degrees.

Class 2. Detectors Responding to the Total Radiant Energy of the Flame

One form of detector operating on total radiation direct from the flame is shown in Figure 5. Here is a diaphragm of corrosive resistant material about 5 mils thick and $2^1/_2$ inches in diameter is welded at its circumference to a ring of the same kind of material, but thicker. This assembly is mounted to a housing which serves as a support and also a means of dissipating heat. Radiant energy from the flame under observation falls on the diaphragm heating it. Because of the configuration, the center of the diaphragm reaches a higher temperature than the circumference causing the diaphragm to "dish". A force in the left-hand direction is applied at the center of

Figure 6. Application of diaphragm and ring-type flame detector to oil flames

Figure 8. Application of bimetal spiral, total-radiation type flame detector to a gun-type oil burner

Figure 9. Flame detector responsive to luminous radiation utilizing a photoemissive photo tube

the diaphragm by means of a coil spring, through a metal ribbon which is secured at one of its ends to the coil spring, passes over a roller and is secured at the other of its ends to the center of the diaphragm. When the diaphragm dishes under heat there is clockwise motion of the roller and the arm secured to it, effecting closure of the switch contacts and somewhat later, engagement of the "hot stop". Further heating of the diaphragm results in slippage of the ribbon on the roller. Hence, here again the motion of the flame detector is coupled to the switch through a "slip friction element". Upon cooling of the diaphragm there is immediate counter-clockwise motion of the switch which continues until the "cold stop" is engaged. Further motion causes slippage of the slip friction element.

This device operates the switch on a change in temperature rather than at a fixed temperature, in the same manner as the switches described previously, but in addition has ambient compensation. Since the diaphragm and supporting ring are made of the same material there is no dishing of the diaphragm unless there is a difference of temperature between the center and circumference. This difference does not exist due to ambient changes except slightly during the transients. Ambient compensation is important in this device since, in some applications, to obtain quick action, the switch might be adjusted to close on a diaphragm temperature change of only 5 to 10 degrees. Ambient changes of this magnitude may commonly occur. Figure 6 shows typical applications.

For good operation this device should be so located that the housing temperature does not ultimately exceed approximately 300 degrees Fahrenheit. This type of detector is used in relatively large size installations where quick response is desirable, as well as is front mounting with close adjacency of the detector to the burner. In this class of application the rate of rise of flue gas temperature in the stack is usually low making the application of the class one detectors more difficult. This type of detector which first appeared in the early 1920's now is being largely obsoleted by the electronic type.

Another detector operating on total radiant energy has as its sensitive element a bimetal device. This detector, shown in Figure 7, has a spherical bulb about $1^1/_4$ inches in diameter with a small cup for a mercury pool formed in the bottom. Two electrodes are extended through a press at the top of the bulb. One electrode dips into the mercury pool. The other is a support for the bimetal element. The bimetal element is made up of a strip of bimetal about 1/16 inch wide and 10 mils thick wound in the shape of a spiral of Archimedes. The bimetal forming the inner portion of the spiral is reverse in action to the bimetal forming the outer portion of the spiral. The inner and outer portions are butt welded together to form one continuous element. Due to this reverse construction there is no resultant motion of the spiral on ambient temperature changes. One-half the inner surface of the bulb is mirrored and the bimetal element is placed in the bulb so that reflected radiation from the mirrored surface is focused only on the inner portion. When detector is subjected to radiation the inner portion of the bimetal heats while the outer portion remains relatively cool causing the spiral to have resultant motion. An electrode is secured to the free end of the spiral and is arranged to dip into the mercury pool when the difference in outer and inner portions of the spiral reach a predetermined amount. Immersion of this last electrode, due to bimetal action, causes completion of the electric circuit extending through the two electrodes and the mercury pool.

It will be noted that the slip friction coupling between actuator and switch is absent in this detector. This switch does, however, have some slip friction effect since it has the ability to respond to change in condition. Radiant energy focused on the inner portion of the bimetal, primarily heats this portion. Some of the heat, however, travels to the compensating outer part of the element raising its temperature as well. If the inner portion is made of low mass and the outer of higher mass there will be a trend for quick action of the movable electrode in one direction to close the switch and then a slow return in the other direction to open the switch as the compensator heats. Obviously if this effect is carried too far and the compensator allowed to reach almost the active bimetal temperature, the switch will be reopened. This must be guarded against. On a decrease in radiation the inner elements cool quickly to, or below, the compensator temperature and opens the switch. As the more massive compensator cools the trend is to reverse the switch action readying the switch for the next cycle. Figure 8 shows a typical application.

Detectors working on this principle first made their appearances in the early 1920's. A more modern version was developed in about 1938. Units of this nature having low mass and being radiant responsive have rather rapid response times. Also, since they are small in size, they may be frequently mounted within the blast tube of an oil burner eliminating the necessity of separate mounting and permitting factory assembly of a burner complete with integral safety combustion controls. It is estimated that about 4 per cent of domestic burners currently manufactured use this form of detector. Other detectors made to respond to total radiant energy and having no moving parts are presently under development by several

Figure 10. Electronic circuit for photoelectric flame detector

manufacturers and may become the subject matter of a future paper.

Class 3. Detectors Responding Primarily to the Luminous Radiation of the Flame

Perhaps the most recent distinctive type of flame detector to make its commercial appearance is the photoelectric type responding to the luminous radiation of flame. This appeared in about 1940. Photo cells frequently used for this service are the Radio Corporation of America type *922*. The photocell is mounted so that it will look into the combustion chamber at the flame. Often the cell is mounted inside the blast tube of a gun-type burner as shown in Figure 9. The cell is usually arranged to operate an electromagnetic relay through a suitable amplifier. This relay then performs the required functions in the remainder of the combustion control circuit.

An electronic circuit suitable for this application is shown in Figure 10. This circuit uses a type *2050* or *2D21* thyratron. The capacitor C is charged by grid current through the thyratron through the path *a,b,d,e,f,g*, during the portion of the a-c cycle when the bottom end of the transformer is positive. This charge is in a direction to make the top plate of the capacitor negative with respect to the bottom plate.

The capacitor also is charged by photocell current through the path *h,i,e,f,g*, during the portion of cycle when the top end of the transformer is positive. This current charges the capacitor in a direction to make the top plate positive with respect to the bottom plate. Since the two charging currents are in opposite directions, the resultant magnitude and direction of voltage appearing across the capacitor will depend upon the relative magnitude of the two charging currents. When the photocell is dark the capacitor will be negative at the top plate and will approach the peak value of the voltage *a,g*. This voltage is of sufficient magnitude to bias the tube past cut off and hold the thyratron from firing. When the photocell is illuminated, the top plate of the capacitor becomes less negative thereby decreasing the amount of negative grid voltage on the tube. When there is sufficient illumination, the grid voltage will reach the firing point and the thyratron will fire pulling in the relay. This firing point corresponds to about 10 to 15 foot candles of illumination on the photocell.

Since the thyratron fires only on positive alternations, a capacitor and current limiter are shunted around the relay coil to eliminate chatter. It should be noted that only d-c effects are utilized to obtain grid bias and signal. Symmetrical a-c effects over the course of a cycle cancel each other out. This makes the photocell circuit quite independent of lead capacity and resistance across the photocell mount, which is obviously highly desirable in dirty locations and under various mounting arrangements.

Since the photocell is small in size it too can be mounted directly within the blast tube of a burner, making for ease of installation and the possibility of locating the entire combustion control integral with the burner. Also, since the response is substantially instantaneous, the remainder of the combustion control may be simplified as explained later. It is estimated that about 2 per cent of currently installed burners are using this type of detector.

Figure 11. Electronic circuit for flame-conduction type flame detector

Class 4. Detectors Responding to the Electrical Conduction of the Flame

Still another form of flame detector works on the principle of flame conduction. As shown in Figure 11, a flame electrode of heat resisting noncorrosive material is well insulated from ground and suspended into the flame to be detected. The flame acts as a rectifier of high internal impedance and may be used the same way as the photocell in the arrangement previously described. The flame acts as the cathode of a diode tube and the suspended electrode as the plate.

Using the basic idea of the photocell circuit but reversing the capacitor and flame sensitive device in order to place the flame at ground potential, the circuit shown results.

When flame is absent, the capacitor is charged by grid current with the bottom plate negative to a value approaching the peak voltage *a,h*. This results in a grid cathode voltage around zero volts and causes the tube to fire. When flame is present, the capacitor is charged when the top end of transformer is plus along the path *h,i,j,e,k,g*, through the rectifying flame. The capacitor voltage then approaches the peak voltage *h,g* producing a negative grid to cathode voltage, cutting the tube off.

It will be noted that the relay action is opposite in this case to that of the photocell. Here, when flame is present, the relay drops while in the former case where flame was present the relay pulled in.

The flame conduction-type detector is not generally suited to oil flames because of the deleterious effect of the oil flame on the electrode and the failure of the flame rod insulator due to dirty products of combustion. This form of detector which first made its commercial appearance in about 1931 finds its primary application in checking gas pilot flames on large installations.

Both the photoelectric and the flame-conduction type detectors respond substantially instantaneously. For oil burning equipment this is quite advantageous in that it permits simplification of the combustion control as well as providing a greater margin of safety.

With the thermal responsive elements of the class 1 and 2 varieties, when flame failure occurs, some interval of time in the nature of 10 to 30 seconds is required for the flame detector to respond and make this fact known to the remainder of the combustion control. During this time, atomized fuel is being delivered to a hot combustion chamber. If this time is too long, there is danger of obtaining a rich enough mixture to ignite with violence from the hot combustion chamber and in any event after about five seconds, it is somewhat hazardous to ignite these un-

burned vapors even with electrical means. Consequently, it is necessary to either shut down on a safety lockout or purge the combustion passages before another attempt is made to restart the burner. On the other hand, when the flame detector responds instantaneously, as in the case of the class 3 and 4 detectors, electric ignition can be connected immediately upon flame failure, to re-ignite the flame without interruption. Thus recycling on flame failure may be obtained without complicating the control with a means for purging or scavenging burner.

It should be pointed out that electronic elements are presumed to fail either conductive or nonconductive and, therefore, in systems employing electronic circuits, means must be provided to make the system fail safe under either of these conditions. This may be accomplished with "cold check" devices, a discussion of which, as has been said, is beyond the scope of this paper.

The present deterent to wide applications of electronic domestic controls is the fact that the electronic components are expendable and that service personnel is not experienced in servicing electronic equipment. It appears that from the safety aspect, the high-speed response afforded by the electronic devices is not required on domestic size plants.

No Discussion

Spring and Damping Coefficients of Synchronous Machines and Their Application

LEE A. KILGORE
FELLOW AIEE

EUGENE C. WHITNEY
MEMBER AIEE

Synopsis: This paper develops simple formulas for spring and damping constants of synchronous machines. These formulas include the effects of induced currents in the damper winding and field. An approximation to the effect of primary resistance in producing a negative damping torque is given. An equivalent circuit is given which can represent accurately the mechanical system of several engine-driven generators or compressors operating in parallel. It is concluded that the conventional representation of synchronizing power as full-load power over full-load angle is sufficiently accurate for most cases, but that it is well to have a more accurate method for special cases.

IT HAS long been recognized that synchronous machines connected to each other or to a system exhibit electrical torques giving a spring action (torques proportional to angular displacement) and a damping action (torques proportional to velocity). The spring action together with the inertia results in a torsional natural frequency of the order of 1-to-4 cycles per second. In the application of synchronous motor-driven compressors and engine-driven generators, the compressor or engine torques may have components which could coincide with the natural frequency and give trouble from excessive current pulsation.

The conventional method of dealing with these problems is to use a synchronizing coefficient (spring constant) determined by full-load power over full-load electrical displacement angle. In generator practice, the spring constant is P_r which is the kilowatts per electrical radian, where

$$P_r = \frac{KVA \times PF}{\text{efficiency} \times \delta}$$

where the displacement angle in radians is

$$\delta = \tan^{-1} \frac{IX_q \cos \theta}{E_t + IX_q \sin \theta} \qquad (1)$$

For very low frequency oscillations (less than one cycle per second) it would be apparent that the slope of the power angle curve should be used for small angular oscillations which give in general a lower value than the above value. For higher frequencies of oscillation, currents are induced in the field and damper windings which tend to stiffen the spring action and may give values under load higher than the conventional method.

A more exact method is given here which should serve as a guide where the conventional methods may be safely used and as a tool for more accurate evaluation where needed. The usual assumption also treats each machine as if it were connected to an infinite system, whereas a method will be given here for using the constants determined for an infinite system to evaluate the effects of a limited number of other machines.

Neglecting primary resistance and assuming an infinite bus, the effects of induced rotor currents may be included as derived in Appendix I. This involves determining effective direct and quadrature resistances and reactances at the oscillation frequency (neglecting primary resistance). These are essentially the same constants used by the synchronous motor designer in calculating starting performance at a corresponding rotor frequency. The constants can be determined by locked test at low-primary frequency by measuring the low-frequency impedance and subtracting the primary resistance. The formula for per unit synchronizing torque per electrical radian is then

$$T_s = \left[\left(\frac{X_{qo}}{Z_{qo}^2} - \frac{1}{X_d} \right) E_t^2 \cos^2 \delta + \left(\frac{X_{do}}{Z_{do}^2} - \frac{1}{X_q} \right) E_t \sin^2 \delta + \frac{E_t E_d}{X_d} \cos \delta \right] \qquad (2)$$

In these formulas, unit torque is the torque corresponding to a power in kilowatts numerically equal to rated kilovolt-amperes; where

E_t = terminal voltage

E_d = internal voltage back of synchronous reactance and δ = internal or displacement angle

The damping coefficient is the ratio of per unit torque to per unit speed where speed is expressed as a fraction of rated speed and is equal to

$$T_d = E_t^2 \frac{\omega}{\omega_0} \left[\frac{r_{qo}}{Z_{qo}^2} \cos^2 \delta + \frac{r_{do}}{Z_{do}^2} \sin^2 \delta \right] \qquad (3)$$

The effect of line reactance between one machine and infinite system may be handled by adding the line reactance to the impedances used and using E_t as the system voltage.

The spring and damping constants are given in Figure 1 for typical generators with both the connected and nonconnected type dampers. The curves are based on $X_d = 1.22$; $X_q = 0.74$; and constants at 5 cycles of $X_{do} = 0.27$; $X_{qo} = 0.60$; $r_{do} = 0.20$; $r_{qo} = 0.27$, determined by locked line-to-line tests for a machine with nonconnected damper windings.

Figure 2 shows how these spring constants compare with the conventional

Figure 1 (left). Curves of synchronizing and damping coefficients

Figure 2 (right). Synchronizing coefficients as a fraction of the conventional value

full load synchronizing power coefficient.

For synchronous motors, high-resistance damper windings of the connected type are used; and the synchronizing coefficients of Figure 2 for connected dampers may be used except the frequencies of the curve should be multiplied by about three in the typical case at full load. It should be observed that these curves are only typical, and individual machines may vary appreciably.

For the main-firing impulse of a diesel engine with a typical frequency of above 15 cycles per second, the error in the spring constant by conventional methods will be appreciable, but it is of little consequence since there is no chance of resonance with the machine natural frequency. In the range of 1.5 to 4 cycles, where there is a chance of resonance, the torque components in a diesel are those at revolutions per minute and half revolution-per-minute frequency due to irregularities in fuel injection. In this range the error in the conventional method is usually not great at full load, and at no load the approximate coefficient calculated as E_t^2/X_s is found to give fair results.

One or two cases are known where some trouble was encountered on older synchronous motors with low-resistance dampers where the spring constant was some 25 per cent higher than the conventional value.

In certain cases the damping coefficient given above must be reduced due to the negative damping effect of the primary resistance. The correction may be approximated as derived in Appendix II. Using the transient reactance of the machine and the voltage back of transient reactance, we can calculate a braking speed torque curve as if the primary were short circuited through line impedance and the primary resistance. The slope of this curve at full speed gives the change in torque per unit change in speed or the negative damping coefficient. This is equivalent to taking this "braking" torque at line frequency minus oscillation frequency, minus the value at line frequency, plus oscillation frequency, divided by the per unit difference in speed at these frequencies (or twice oscillation frequency divided by rated frequency). This coefficient can be shown to be approximately equal numerically to the braking torque calculated as before at full speed.

The approximate equation for this negative damping coefficient can be written as

$$T_{dn} \approx \frac{(E_d')^2}{(X_d')^2+r_1^2}\, r_1$$

A high value of primary resistance (such as might be encountered on a small machine or a large machine on a long line) $r_1=0.05$ would result in about 0.5 to 0.9 negative damping coefficient. Figure 1 curve "A" or "D" indicates values of 5 to 25 for the positive damping for typical generators. For synchronous compressor motors with high-resistance damper windings, the damping coefficient might be as low as 2, but here even with the high line resistance of 0.05 (assumed above) the negative damping would be about 0.3 or less due to the higher transient reactance.

In the compressor applications it has been customary to use a damping torque 10 per cent of the synchronizing torque. This is equivalent to using a resistance 0.1 of X_c in the equivalent circuit of Figure 3 or a damping coefficient of 0.1 of $2\pi f_c\,(2H)$. For typical values of H, this would give a damping coefficient of 4 which is higher than calculated here for motors with high-resistance dampers (as used in present-day practice to obtain low inrush). Fortunately in compressor applications the natural frequency is kept sufficiently removed from the torque impulse frequencies that the resistance effects are small and the conventional figure leads to little error.

In diesel engine practice some[1] have used an approximate damping coefficient 0.01 times the synchronizing torque in inch, pounds, radians. This is equivalent to a per unit damping coefficient of 3.77 times the per unit synchronizing coefficient or about eight in a typical case. Referring to Figure 1, this will be seen to be a generally conservative figure.

Parallel Operation of Engine Driven Generators

Particularly in diesel engine application it is desirable to have a means of considering the effect of one machine on another where there are a limited number of machines on the system. The method given here is based on representing each machine by an equivalent circuit, in which its inertia is represented by an inductance (L) its spring or synchronizing action by a condenser (C) and its damping by a resistance (R), see Figure 3. Unit current in this circuit would represent unit velocity (equal to rated velocity)

and unit voltage would correspond to rated torque.

It is well in thinking of several generators on a bus to visualize a synchronously rotating flux in each machine corresponding to the common terminal voltage. As each rotor moves relative to this flux, voltages, and currents are induced which are seen to be the same as for a single machine on an infinite bus.

Referring to Figure 4, each machine can be represented as a network. The common current which flows through each network in series is analogous to the reference velocity of the synchronously rotating flux corresponding to terminal voltage. The velocity of each machine is represented by the current in each inductance. The current in the capacitive branch then represents the relative velocity of the unit with respect to the reference.

The torque impulses of one engine at a time should be considered and the machine in which the impulse occurs will be referred to as the source machine. The torque impulse is represented as a voltage applied in the inductive branch, since the torque tries to change the velocity. This puts the series impedance of the other networks in parallel with the capacitive branch of the source machine. In mechanical terms, the torque developed between this machine and the others depends on its relative velocity and its spring and damping constants.

Examining the equivalent circuit, Figure 4, it is apparent that the resonant frequency will be affected by the other machines. In fact there will be as many natural frequencies as machines. All of these frequencies will be somewhat different from that of each machine alone on an infinite system.

The exact solution can be determined by solving the complete circuit for a series of frequencies. This can be done very readily on an a-c calculating board. We can, however, obtain certain information by simplifying the circuit by approximate relations.

The effect of the inertias is to cancel the spring constants leaving a net plus or minus value for each machine, which when combined would be equal and opposite to that of the source machine at resonance. Hence, we can add up the values of $X_eX_1/(X_1-X_e)$ to get the value which must be equal to $-X_eX_1/(X_1-X_e)$ for the source machine. We can plot $f_oP_r/(f_o^2-f_n^2)$ for each machine including the source machine, and these must add up to zero for resonance which is equivalent to the method given in reference number 1. This at least gives an approximate indication of where resonance will occur.

The next step would be to determine the approximate damping.

If any machine has the same natural frequency f_n (on an infinite bus) as the machine with source of torque pulsation, its impedance in the equivalent circuit will be very high compared with the others, and it will take most of the voltage which appears across the capacity and resistance of the source unit. Hence, the two machines will oscillate in angles approximately in inverse proportion to their inertia constants.

Even though the natural frequencies do not match, the impedance representing the combined machines may parallel with the capacity of the source machine so as to give resonance. Except where two natural frequencies are nearly coincident, the combined resonance frequency will differ sufficiently from the individual natural frequencies that we can use the above approximation for the effective spring constant (or X_e) and we can use $X_1^2R/(X_1-X_e)$ as an approximation to the damping of each unit in the series circuit. The limiting value of series resistance in resonance is X_1^2/R and if the value approaches this then the equation must be solved for the exact series impedance.

The combined resistance and reactance designated by R_Σ and $X_{e\Sigma}$ is then determined for the other machines and paralleled with the values of the source machine R_s and X_{es}.

Assuming R_Σ to be small (say not over 30 per cent of $X_{e\Sigma}$) then the resistance is

$$\frac{X_{es}X_s(R_s+R_\Sigma)}{(X_{e\Sigma}+X_{es})^2}+\frac{RX_{es}+R_sX_{e\Sigma}}{X_{e\Sigma}+X_{es}}$$

The ratio of the X_e of the source machine to this resistance gives an amplification factor to be applied to the motion as compared with that which would be obtained if the inertia alone limited the motion.

In solving the circuit of Figure 4 all values of X_1, X_e, T_d, and R must be placed on a common kilovolt-ampere base. For example, if a 1,000-kva base is selected and unit number 1, 2, or 3 is actually 625 kva then the values for this unit must be multiplied by 625/1,000 to be on the 1,000-kva base.

List of Symbols

E_e = see Figure 3
E_d = per unit excitation on the direct axis for an unsaturated machine
E_1 = see Figure 3
E_t = per unit terminal voltage of machine
H = inertia constant. See Figure 3
I = per unit machine line amperes based on rated amperes of the machine
i = unit current in the equivalent circuit corresponding to rated velocity
KVA = rated machine kilovolt-ampere
P_r = synchronizing coefficient in kilowatts per electrical radian
Per Unit = times normal rated value. 1 per unit = rated value
R = damping resistance in the equivalent circuit
r_d = per unit resistance direct axis
r_q = per unit resistance quadrature axis
Torque = 1.0 per unit torque corresponds to a kilowatt input equal to rated kilovolt-ampere at 1.0 power factor
WR^2 = weight times radius of gyration squared in pounds feet squared
X_e = capacitive reactance in the equivalent circuit
X_d = per unit direct axis synchronous reactance
X_1 = inductive reactance in the equivalent circuit
X_q = per unit quadrature axis synchronous reactance
Z_d = per unit direct axis impedance
Z_q = per unit quadrature axis impedance
δ = internal machine angle due to load in electrical radians $=\tan^{-1}\dfrac{IX_q\cos\theta}{E_d+IX_q\sin\theta}$
PF = power factor = $\cos\theta$
θ = power factor angle
$\omega_o=2\pi f_o$ = velocity in electrical radians per second at oscillation frequency
$\omega=2\pi f$ = velocity in electrical radians per second at rated machine frequency

Figure 4 (right). Equivalent circuit of a number of generators on a system

Appendix I. Derivation of Spring and Damping Coefficients

Neglecting primary resistance and assuming a sinusoidally distributed winding and an infinite bus, the primary voltage E_1 produces a constant rotating field of flux. The rotor is visualized as oscillating sinusoidally about a synchronously rotating average position through a small angular amplitude Δ. The angular change is then $\Delta \sin \omega_o t$. The direct axis linkages ψ_d will consist of a constant term plus an alternating component $\Delta E_1 \sin \delta \sin \omega_o t$. The current also will have an average component I_d and an alternating component due to the pulsation in ψ_d which may be calculated as in any simple alternating circuit providing we know the equivalent resistance and reactance as viewed from the primary (neglecting primary resistance). These constants[a] are written with the subscript o to indicate oscillation frequency and are equivalent to those used in starting performance calculations at the same rotor frequency.

The instantaneous values of the direct and quadrature axis flux linkages and currents then are written as

$$\psi_d = E_d \cos \delta - E_1 \sin \delta \sin \omega_o t$$

$$\psi_q = E_1 \sin \delta + E_d \cos \delta \sin \omega_o t$$

$$i_d = I_d - \Delta E_1 \sin \delta \left(\frac{r_{do}}{Z_{do}^2}\right) \times \cos \omega_o t - \Delta E_1 \sin \delta \left(\frac{X_{do}}{Z_{do}^2}\right) \sin \omega_o t$$

$$i_q = I_q + \Delta E_d \cos \delta \left(\frac{r_{qo}}{Z_{qo}^2}\right) \times \cos \omega_o t + \Delta E_1 \cos \delta \left(\frac{X_{qo}}{Z_{qo}^2}\right) \sin \omega_o t$$

$$I_q = \frac{E_1 \sin \delta}{X_q}$$

and

$$I_d = \frac{E_1 \cos \delta - E_d}{X_d}$$

$$T = \psi_d I_q - \psi_q I_d{}^*$$

Oscillation frequency components of torque

$$\Delta E_1^2 \left[\cos^2 \delta \frac{r_{qo}}{Z_{qo}^2} + \sin^2 \delta \frac{r_{do}}{Z_{do}^2}\right] \cos \omega_o t +$$

$$\Delta E_1^2 \left[\cos^2 \delta \frac{X_{qo}}{Z_{qo}^2} + \sin^2 \delta \frac{X_{do}}{Z_{do}^2}\right] \sin \omega_o t +$$

$$\Delta E_1^2 \left[\frac{\sin^2 \delta}{X_q} - \frac{\cos^2 \delta}{X_d}\right] \sin \omega_o t +$$

$$E_1 E_d \frac{\sin \delta}{X_d} \cos \omega_o t$$

Damping constant = coefficient of $\cos \omega_o t + \Delta \omega_o$

$$T_d = \frac{\omega E_1^2}{\omega_o} \left[\cos^2 \delta \frac{r_{qo}}{Z_{qo}^2} + \sin^2 \delta \frac{r_{do}}{Z_{do}^2}\right]$$

Spring constant

$$T_s = \left[\left(\frac{X_{qo}}{Z_{qo}^2} - \frac{1}{X_d}\right) E_1^2 \cos^2 \delta + \left(\frac{X_{do}}{Z_{do}^2} - \frac{1}{X_q}\right) E_1^2 \sin^2 \delta + \frac{E_1 E_d \cos \delta}{X_d}\right]$$

Figure 5. Voltage vector diagram showing pulsating components

Appendix II. The Effect of Primary Resistance

The primary resistance is generally small, but it does produce a negative damping coefficient which in some cases can be appreciable. The major effect of the primary resistance may be evaluated by assuming the pulsating armature current to be the same as would be obtained if the field resistance to reactance ratio were negligible and the oscillation frequency currents in the damper windings are neglected. The currents are then the same as would be calculated using the assumption that the direct axis voltage back of transient reactance is constant.

The reaction of this voltage with the primary voltage gives the synchronizing torque, but feeding back through the system and the primary resistance it produces a torque in phase with the velocity. The assumption of constant flux linkage on the field is equivalent to assuming a fixed rotating flux in an induction motor primary or in the field of an electric coupling. The derivation for the torque reactions under these conditions was given in reference 5. It was shown there that the damping torque could be determined by the speed or slip torque curve assuming the winding short circuited through its resistance including in this case any line impedance. The difference in torque at the slip frequency plus oscillation frequency and at slip frequency minus oscillation frequency, divided by twice the per unit oscillation frequency gives the negative damping coefficient. This solution neglects some small effects due to the change of ψ_d and ψ_q due to line drop and the change of primary voltage drop due to secondary resistance.

Discussion

R. V. Shepherd (General Electric Company, Schenectady, N. Y.): The correctiveness of the authors' novel approach to the determination of damping and synchronizing torques is confirmed by the fact that Mr. Park's general equation[1] for the electrical torque for small angular deviations from the average operating angle reduces to the authors' equations for the case where primary resistance is zero.

For usual values of load angle δ the contribution of the direct axis to damping is not great; in fact, for low pulsation frequencies the damping torque coefficient given in equation 3 of the paper is sensibly equal to equation 3 evaluated for $\delta = 0$, which, in turn, is equal to the per-unit quadrature-axis torque divided by the per-unit pulsation frequency.

It should be noted that the authors' derivations hold only for zero primary resistance and for small deviations from the average operating load angle. While zero primary resistance is never realized in practice, I have used the simplified formula with success for a number of years for the lower values of pulsation frequency usually encountered. However, I have not previously had occasion to consider pulsation frequencies approaching the machine rated frequency, but several checks which have been made indicate that the approximate equations diverge from the solution of Park's equation including resistance, at per-unit pulsation frequencies of the order of 0.5 and higher. That this might be expected can be inferred from the following:

At no-load unity-power-factor operation, Park's equation reduces to

$$\frac{\Delta T}{\Delta \delta} = \frac{e^2(1-h^2)X_d(jh) + jhe^2 r_1}{(1-h^2)X_d(jh)X_q(jh) + jhr_1[X_d(jh) + X_q(jh)] + r_1^2}$$

Where

h = per-unit pulsation frequency
r_1 = primary resistance
$X_d(jh)$ and $X_q(jh)$ = direct- and quadrature-axis impedance functions at pulsation frequency h

When $h = 1.0$

$$\frac{\Delta T}{\Delta \delta} = \frac{e^2}{X_d(jh) + X_q(jh) - jr_1}$$

This is considerably different than the solution obtained for $r_1 = 0$, namely

$$\frac{\Delta T}{\Delta \delta} = \frac{e^2}{X_q(jh)}$$

The solution of Park's equation requires laborious calculations; hence the authors' braking-torque coefficient correction to account for primary resistance simplifies these calculations considerably. Here again however, it seems reasonable to expect that this approximation will hold only over a reasonable range of pulsation frequency and for limited values of primary resistance. Has this been investigated?

In practice, deviation from the average operating angle on diesel-driven generators is determined by the allowable current or power pulsation, or angular deviation. In general, the values used are such as to make the deviations from the average angle small so that this assumption, on which the equations are based, does apply.

L. A. Kilgore and **E. C. Whitney:** We appreciate Mr. Shepherd's comment that he can confirm this derivation for small angles of oscillation starting with Park's equation[1] and neglecting primary resistance. These assumptions were stated in the paper. Mr. Shepherd seems to agree with the approximation using the braking-torque coefficient but questions the range of frequency and resistance over which this is valid.

Perhaps at some later date someone could start with the exact solution and show these limitations. We have no exact experimental proof but have made certain very important calculations on large machines using this approximation, which worked out well.

It is seldom required to determine the damping accurately at frequencies above the usual natural frequencies of several cycles per second.

Per-Unit Inductances of Synchronous Machines

H. S. KIRSCHBAUM
ASSOCIATE AIEE

IN AN excellent series of papers[1,2] Mr. A. W. Rankin clarified and unified the situation regarding the meaning of the various per-unit impedances which have been used in synchronous machine theory. Heretofore, there had been confusion arising from the use of rotor base quantities which result in nonreciprocal mutual inductances between rotor and stator windings. The purpose of this paper is twofold. First, the synchronous machine equations will be developed from fundamental considerations using actual stator and rotor inductances rather than per-unit quantities. A critical examination will be made of the transformation from phase to direct and quadrature axis quantities with the physical implications of the transformation kept in mind. The transformation from phase to direct and quadrature axis currents is slightly different from that used by previous authors.[3] This was necessary in order to preserve the reciprocity of mutuals. Secondly, base rotor quantities will be chosen in such a manner that all the per-unit self-inductances on the direct axis are numerically equal to the direct axis synchronous inductance in per unit. The per-unit mutual inductances on the direct axis are then equal numerically to the coefficient of coupling between the two windings involved, times the direct axis synchronous inductance in per unit.

The Flux Linkage Equations

In writing the voltage equations of any or all the circuits on both sides of the air gap of a synchronous machine, it is usually most convenient to write them in terms of the time rate of change of the flux linkages with the various circuits. This necessitates a knowledge of all self and mutual inductances in the machine. The analysis which follows will be made for an ideal synchronous machine[4] as defined by Park.

When, in such a machine as illustrated in Figure 1, the direct axis of the rotor is coincident with the axis of phase a, the self-inductance of phase a is maximum since the permeance of the magnetic path of the phase also is a maximum. When the quadrature axis of the rotor is coincident with phase a its self-inductance is a minimum because the permeance of the magnetic path of phase a also is a minimum. Since each phase consists of N sinusoidally distributed turns, the self-inductance of phase a will vary as a cosine function of the angle 2θ in the following manner

$$L_{aa} = L_s + \Delta L_s \cos 2\theta \tag{1A}$$

In a similar manner the self-inductances of phase b and c can be written

$$L_{bb} = L_s + \Delta L_s \cos\left(2\theta + \frac{2\pi}{3}\right) \tag{1B}$$

$$L_{cc} = L_s + \Delta L_s \cos\left(2\theta - \frac{2\pi}{3}\right) \tag{1C}$$

When the direct axis of the rotor makes an angle of $-\pi/6$ radians with the axis of phase a as shown in Figure 2(A) the mutual inductance between phase a and phase b is a maximum. When the direct axis of the rotor makes an angle of $\pi/3$ radians with the axis of phase a the mutual inductance between phases a and b is a minimum. Thus the mutual inductance between phases a and b can be written

$$L_{ab} = L_m - \Delta L_m \cos\left(2\theta - \frac{2\pi}{3}\right) \tag{2A}$$

In a similar manner

$$L_{bc} = L_m - \Delta L_m \cos 2\theta \tag{2B}$$

$$L_{ca} = L_m - \Delta L_m \cos\left(2\theta + \frac{2\pi}{3}\right) \tag{2C}$$

Tests and calculations on synchronous machines show that the difference between the minimum and maximum self-inductance per phase is equal to the difference between minimum and maximum mutual inductance between phases. Or

$$\Delta L_s = \Delta L_m = \Delta L \tag{3}$$

In the ideal machine with sinusoidally distributed phase windings this is exactly true. Using these inductance coefficients the flux linkages with phases a, b, and c, resulting from the flow of armature currents alone are

$$\psi_{a1} = L_{aa}i_a - L_{ab}i_b - L_{ac}i_c \tag{4A}$$

$$\psi_{b1} = -L_{ba}i_a + L_{bb}i_b - L_{bc}i_c \tag{4B}$$

$$\psi_{c1} = -L_{ca}i_a - L_{cb}i_b + L_{cc}i_c \tag{4C}$$

These flux linkage equations can be written in terms of the direct axis, quadrature axis and zero sequence inductances per phase all of which are also directly measurable from the armature terminals. It is preferable to use these inductances since these are the ones most generally used and recognized by design and application engineers. Consequently, the flux linkages with phase a resulting from the flow of phase currents are as follows

$$\psi_{a1} = \frac{2}{3}\left[\frac{L_d + L_q}{2}\right]\left(i_a - \frac{i_b + i_c}{2}\right) + \frac{2}{3}\left[\frac{L_d - L_q}{2}\right]\left[i_a \cos 2\theta + i_b \cos\left(2\theta - \frac{2\pi}{3}\right) + i_c \cos\left(2\theta + \frac{2\pi}{3}\right)\right] + \frac{1}{3}L_0(i_a + i_b + i_c) \tag{5}$$

where

$$L_d = \left[L_s + L_m + \frac{3}{2}\Delta L\right] \tag{6}$$

$$L_q = \left[L_s + L_m - \frac{3}{2}\Delta L\right] \tag{7}$$

Paper 50-38, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 21, 1949; made available for printing November 30, 1949.

H. S. KIRSCHBAUM is Assistant Professor of Electrical Engineering with the Ohio State University, Columbus, Ohio.

Figure 1. Ideal synchronous machine showing assumed positive directions of currents in the various windings

$$L_b = L_a - 2L_m \tag{8}$$

The flux linkages with phase b also can be written from equation 5 by advancing the subscripts of all currents by one phase letter and using for θ, the angle between the direct axis of the rotor and the axis of phase b. In a similar manner the flux linkages for phase c can be written.

In addition to the flux linkages with the stator phases resulting from the flow of stator currents, there are flux linkages with the stator phases because of the presence of rotor currents.

From Figure 1, it is obvious that these are, for phase a

$$\psi_{ra} = [L_{afa}I_{fa} + L_{a1d}I_{1d} + \ldots + L_{and}I_{nd} + \ldots] \cos\theta - [L_{a1q}I_{1q} + L_{anq}I_{nq} + \ldots] \sin\theta \tag{9}$$

Those for phases b and c are readily derivable. Since the maximum mutual inductances between a given rotor circuit and any of the stator phases are numerically equal, the flux linkages with phase b due to the presence of rotor currents can be written from equation 9 by using for θ, the angle between phase b and the direct axis of the rotor. Similarly for phase c. The total flux linkages with phase a due to both rotor and stator currents will be given by the sum of equations 5 and 9.

The flux linkages with the rotor windings on the direct and quadrature axes are as follows

$$\Psi_{fd} = L_{ffd}I_{fd} + L_{f1d}I_{1d} + \ldots + L_{fnd}I_{nd} + \ldots + L_{fad}\left[i_a \cos\theta + i_b \cos\left(\theta - \frac{2\pi}{3}\right) + i_c \cos\left(\theta + \frac{2\pi}{3}\right)\right] \tag{10}$$

$$\Psi_{nd} = L_{nfd}I_{fd} + L_{n1d}I_{1d} + \ldots + L_{nnd}I_{nd} + \ldots + L_{nad}\left[i_a \cos\theta + i_b \cos\left(\theta - \frac{2\pi}{3}\right) + i_c \cos\left(\theta + \frac{2\pi}{3}\right)\right] \tag{11}$$

$$\Psi_{nq} = L_{n1q}I_{1q} + L_{n2q}I_{2q} + \ldots + L_{nnq}I_{nq} + \ldots - L_{naq}\left[i_a \sin\theta + i_b \sin\left(\theta - \frac{2\pi}{3}\right) + i_c \sin\left(\theta + \frac{2\pi}{3}\right)\right] \tag{12}$$

Transformation to Direct and Quadrature Axis Quantities

It is possible by means of a suitable transformation to replace the actual system of stator currents and flux linkages by an equivalent system which when viewed from the rotor appears identical to the actual system. This transformation, which is well known, will be written as follows

$$\psi_d = A\left[\psi_a \cos\theta + \psi_b \cos\left(\theta - \frac{2\pi}{3}\right) + \psi_c \cos\left(\theta + \frac{2\pi}{3}\right)\right] \tag{13}$$

$$\psi_q = -A\left[\psi_a \sin\theta + \psi_b \sin\left(\theta - \frac{2\pi}{3}\right) + \psi_c \sin\left(\theta + \frac{2\pi}{3}\right)\right] \tag{14}$$

$$i_d = B\left[i_a \cos\theta + i_b \cos\left(\theta - \frac{2\pi}{3}\right) + i_c \cos\left(\theta + \frac{2\pi}{3}\right)\right] \tag{15}$$

$$i_q = -B\left[i_a \sin\theta + i_b \sin\left(\theta - \frac{2\pi}{3}\right) + i_c \sin\left(\theta + \frac{2\pi}{3}\right)\right] \tag{16}$$

Using this transformation in conjunction with the equations for stator and rotor flux linkages, it is possible to write the linkage equations for the direct and quadrature axis circuits. They will be written for only the direct axis since those for the quadrature axis are similar.

$$\Psi_{fd} = [L_{ffd}I_{fd} + L_{f1d}I_{1d} + \ldots + L_{fnd}I_{nd} + \ldots] + \frac{1}{B} L_{fad} i_d \tag{17}$$

$$_{nd} = [L_{nfd}I_{fd} + L_{n1d}I_{1d} + \ldots + L_{nnd}I_{nd} + \ldots] + \frac{1}{B} L_{nad} i_d \tag{18}$$

$$\psi_d = \frac{3}{2} A\,[L_{afd}I_{fd} + L_{a1d}I_{1d} + \ldots + L_{and}I_{nd} + \ldots] + \frac{A}{B} L_a i_d \tag{19}$$

Examination of equations 17 to 19 will show that the product of A and B must equal two-thirds in order that the reciprocity of mutuals be maintained. This follows from the fact that L_{nad} equals L_{nad}.

If A is set equal to two-thirds, then B must equal unity. Physically this may be interpreted with the aid of Figure 3. From the point of view of an observer on the rotor, the current distribution along the periphery of the stator, resulting from the flow of i_a, i_b, and i_c in phases a, b, and c respectively, has been replaced by an identical current distribution resulting from the flow of i_d and i_q in two sinusoidally distributed windings having N turns each. The winding carrying i_d has its axis coincident with the direct axis of the rotor and the winding carrying i_q has its axis coincident with the quadrature axis of the rotor. As each of these equivalent coils has the same number of turns as any of the actual stator phases, the mutual inductance between any rotor circuit on the direct axis and the equivalent direct axis stator circuit will be equal to the maximum mutual inductance between said rotor circuit and a stator phase. This also holds true for the quadrature axis.

With A and B equal to two-thirds and unity respectively the stator and rotor linkages on the direct axis are

$$\Psi_{fd} = L_{ffd}I_{fd} + L_{f1d}I_{1d} + \ldots + L_{fnd}I_{nd} + \ldots + L_{fad}i_d \tag{20}$$

Figure 2(A). Position of rotor for maximum mutual inductance between phases a and b

Figure 2(B). Position of rotor for minimum mutual inductance between phases a and b

$$\Psi_{nd}=L_{nfd}I_{fd}+L_{n1d}I_{1d}+\ldots+L_{nnd}I_{nd}+\ldots+L_{nsd}i_d \quad (21)$$

$$\psi_d=L_{afd}I_{fd}+L_{a1d}I_{1d}+\ldots+L_{and}I_{nd}+\ldots+\frac{2}{3}L_d i_d \quad (22)$$

All mutuals are thus reciprocal and the quantity $(2/3)L_d$ is the self-inductance of the equivalent direct axis coil. It can be shown that the average self-inductance per phase, L_s is equal to twice the average mutual between phases plus the slot leakage inductance per phase, or

$$L_s=2L_m+L_l \quad (23)$$

Consequently

$$\frac{2}{3}L_d=(L_s+\Delta L)-\frac{1}{3}L_l \quad (24)$$

The self-inductance of the equivalent direct axis stator coil is less than the maximum self-inductance per phase by one-third the slot leakage per phase. This is as it should be since the equivalent windings would be wound 2/3 as many slots each having 3/2 the width of the old ones.

By means of the transformation embodied in equations 13 to 16 the synchronous machine has been replaced by two n-winding transformers, one on the direct axis and one on the quadrature axis. Equations 20 to 22 are independent of θ.

Per-Unit Linkage Equations

Equations 20 to 22 express the linkages per circuit in terms of actual currents and inductance coefficients. This section will describe a transformation to per-unit linkages in terms of per-unit currents and inductances which preserves the reciprocity of the mutual inductances. For all direct axis circuits this transformation results in per-unit self-inductances which are equal to L_d in per unit and in per-unit mutuals which are equal to the coefficient of coupling between the two circuits concerned times L_d in per unit. Similar results can be obtained for the quadrature axis.

Let unit stator phase current and phase voltage be denoted as follows

$$i_{ao}=\sqrt{2}I_{\text{(rated per phase)}} \quad (25)$$

$$e_{ao}=\sqrt{2}E_{\text{(rated per phase)}} \quad (26)$$

Then unit current and voltage for the equivalent direct axis stator coil will be

$$i_{do}=\frac{3}{2}i_{ao} \quad (27)$$

$$e_{do}=e_{ao} \quad (28)$$

One unit of phase reactance will be equal to the ratio of unit phase voltage to phase current

$$x_{ao}=\frac{e_{ao}}{i_{ao}}\omega_o L_{ao} \quad (29)$$

This defines unit phase inductance as the ratio of unit phase reactance to unit stator angular frequency (rated angular frequency).

As a consequence unit phase and equivalent direct axis stator flux linkages are as follows

$$\psi_{ao}=i_{ao}L_{ao} \quad (30)$$

$$\psi_{do}=\psi_{ao}=i_{do}L_{do} \quad (31)$$

Unit inductance for the equivalent direct axis coil then will be

$$L_{do}=\frac{2}{3}L_{ao} \quad (32)$$

These unit quantities are fixed entirely by the machine kilovolt-amperes, voltage and frequency rating. They are not subject to arbitrary choice. However, this does not apply to the rotor circuits. As these circuits generally have no ratings affixed to them (if they do the ratings are fixed by circumstances other than those being considered here), it has been customary to arbitrarily assign unit quantities for rotor currents and flux linkages. In many cases the arbitrary choice results in nonreciprocal mutual inductances. By choosing the following rotor unit quantities, the per-unit mutual inductances will be reciprocal

$$I_{fdo}=\sqrt{\frac{\frac{2}{3}L_d}{L_{ffd}}}\,i_{do} \text{ or } i_{do}=I_{fdo}\sqrt{\frac{L_{ffd}}{\frac{2}{3}L_d}} \quad (33)$$

$$I_{ndo}=\sqrt{\frac{\frac{2}{3}L_d}{L_{nnd}}}\,i_{do} \text{ or } i_{do}=I_{ndo}\sqrt{\frac{L_{nnd}}{\frac{3}{2}L_d}} \quad (34)$$

Figure 3. Equivalent synchronous machine showing assumed positive directions of currents in the various windings

$$\Psi_{fdo}=\sqrt{\frac{L_{ffd}}{\frac{2}{3}L_d}} \quad \psi_{do}=\left[i_{do}\sqrt{\frac{L_{ffd}}{\frac{2}{3}L_d}}\right]i_{do} \quad (35)$$

$$\Psi_{ndo}=\sqrt{\frac{L_{nnd}}{\frac{2}{3}L_d}} \quad \psi_{do}=\left[L_{do}\sqrt{\frac{L_{nnd}}{\frac{2}{3}L_d}}\right]i_{do} \quad (36)$$

Unit flux linkages with all direct axis circuits then can be written in terms of unit current in any of the direct axis circuits.

$$\Psi_{fdo}=\left[L_{do}\frac{\sqrt{L_{ffd}\frac{2}{3}L_d}}{\frac{2}{3}L_d}\right]i_{do}=\left[L_{do}\frac{L_{ffd}}{\frac{2}{3}L_d}\right]I_{fdo}=\ldots=\left[L_{do}\frac{\sqrt{L_{ffd}L_{nnd}}}{\frac{2}{3}L_d}\right]I_{nnd} \quad (37)$$

$$\Psi_{ndo}=\left[L_{do}\frac{\sqrt{L_{nnd}\frac{2}{3}L_d}}{\frac{2}{3}L_d}\right]i_{do}=\left[L_{do}\frac{\sqrt{L_{nnd}L_{ffd}}}{\frac{3}{2}L_d}\right]I_{fdo}=\ldots=\left[L_{do}\frac{L_{nnd}}{\frac{3}{2}L_d}\right]I_{ndo} \quad (38)$$

$$\psi_{do}=L_{do}i_{do}=\left[L_{do}\frac{\sqrt{L_{ffd}\frac{2}{3}L_d}}{\frac{2}{3}L_d}\right]I_{fdo}=\ldots=\left[L_{do}\frac{\sqrt{L_{nnd}\frac{2}{3}L_d}}{\frac{2}{3}L_d}\right]I_{ndo} \quad (39)$$

If equations 20 to 22 are divided by equations 37 to 39 the resulting equations will be per-unit flux linkage equations for the direct axis circuits.

A prime ′ will be used to denote quantities representing per-unit quantities.

$$\Psi_{fd}'=\left[\frac{\frac{2}{3}L_d}{L_{do}}\right]I_{fd}'+\left[\frac{\frac{2}{3}L_aL_{fnd}}{L_{do}\sqrt{L_{ffd}L_{nnd}}}\right]\times I_{1d}'+\ldots+\left[\frac{\frac{2}{3}L_aL_{fnd}}{L_{do}\sqrt{L_{ffd}L_{nnd}}}\right]I_{nd}'+\ldots+\left[\frac{\frac{2}{3}L_aL_{fnd}}{L_{do}\sqrt{L_{ffd}\frac{2}{3}L_d}}\right]i_d' \quad (40)$$

$$\Psi_{nd}' = \left[\frac{\frac{2}{3} L_d L_{afd}}{L_{do}\sqrt{L_{nnd} L_{ffd}}}\right] I_{fd}' + \left[\frac{\frac{2}{3} L_d L_{nid}}{L_{do}\sqrt{L_{nnd} L_{iid}}}\right] I_{id}' + \ldots + \left[\frac{\frac{2}{3} L_d}{L_{do}}\right] I_{nd}' \ldots + \left[\frac{\frac{2}{3} L_d L_{aod}}{L_{do}\sqrt{L_{nnd}\frac{2}{3} L_d}}\right] i_a' \quad (41)$$

$$\Psi_d' = \left[\frac{\frac{2}{3} L_d L_{afd}}{L_{do}\sqrt{L_{ffd}\frac{2}{3} L_d}}\right] I_{fd}' + \left[\frac{\frac{2}{3} L_d L_{aid}}{L_{do}\sqrt{L_{iid}\frac{2}{3} L_d}}\right] I_{id}' + \ldots + \left[\frac{\frac{2}{3} L_d L_{and}}{L_{do}\sqrt{L_{nnd}\frac{2}{3} L_d}}\right] I_{nd}' \ldots + \left[\frac{\frac{2}{3} L_d}{L_{do}}\right] i_d' \quad (42)$$

These equations for the per-unit direct axis flux linkages can be rewritten making use of the following identities

$$\left[\frac{\frac{2}{3} L_d}{L_{do}}\right] = L_d' \quad (43)$$

$$\left[\frac{L_{fnd}}{\sqrt{L_{ffd} L_{nnd}}}\right] = k_{fnd} \quad (44)$$

Equation 43 is recognizable as the definition of the per-unit direct axis synchronous inductance per phase, while equation 44 is the definition of the coefficient of coupling between two of the circuits on the direct axis of the machine.

$$\Psi_{fd}' = L_d' I_{fd}' + k_{fnd} L_d' I_{nd}' + \ldots + k_{fid} L_d' i_d' \quad (45)$$

$$\Psi_{nd}' = k_{nfd} L_d' I_{fd}' + k_{nid} L_d' I_{id}' + \ldots + L_d' I_{nd}' + \ldots + k_{and} L_d' i_d' \quad (46)$$

$$\psi_d' = k_{afd} L_d' I_{fd}' + k_{aid} L_d' I_{id}' + \ldots + k_{and} L_d' I_{nd}' + \ldots + L_d' i_d' \quad (47)$$

Similar expressions for the quadrature axis can be obtained by replacing the subscript d in equations 46 and 47 by the subscript q.

Conclusions

This paper has presented a consistent treatment of per-unit inductance coefficients for synchronous machines. These expressions are derived from similar expressions employing actual units. By choosing base rotor current and flux linkages for any rotor circuit in such a manner that base stored energy for all circuits on the direct axis is the same, the resulting per unit inductances are mutually reciprocal. In particular the choices embodied in equations 33 to 36 result in the very simple expressions of equations 45 to 47. In spite of their simplicity there are still considerable calculations involved in arriving at the coefficients of coupling.

Therefore this is not to be interpreted as a proposal to adopt the aforementioned system, since its implications will have to be explored further in its application to machine transients.

Appendix I. Nomenclature

All quantities in the paper are in actual amperes, henrys, weber turns, and so forth. A prime ′ is used to denote per-unit quantities.

L_{aa}, L_{bb}, L_{cc} = self-inductances of the stator phase circuits

L_{ab}, L_{bc}, L_{ca} = mutual inductances between stator phases

L_s = average stator phase self-inductance

ΔL_s = maximum deviation from the average of the self-inductance of a stator phase

L_m = average mutual inductance between stator phases

ΔL_m = maximum deviation from the average of the mutual inductance between phases

L_d = direct axis synchronous inductance per phase

L_q = quadrature axis synchronous inductance per phase

L_0 = zero sequence inductance per phase

L_l = leakage inductance of stator per phase

L_{and} = maximum mutual inductance between a stator phase and any rotor circuit on the direct axis

L_{anq} = maximum mutual inductance between a stator phase and any rotor circuit on the quadrature axis

L_{nnd}, L_{nnq} = self-inductances of any direct and quadrature axis rotor circuits respectively

L_{nmd}, L_{nmq} = mutual inductances between any two direct or quadrature axis rotor circuits respectively

L_{ao} = unit stator inductance per phase

L_{do} = unit stator inductance of direct axis circuit

k_{and} = coefficient of coupling between any direct axis rotor circuit and the equivalent direct axis stator circuit

k_{nmd} = coefficient of coupling between any two direct axis rotor circuits

i_a, i_b, i_c = stator phase currents

i_d, i_q = stator direct and quadrature axis currents respectively

L_{ffd}, L_{fad} = self inductance of field, mutual inductance between field and armature

I_{nd}, I_{nq} = rotor currents in any direct or quadrature axis rotor circuits respectively

i_{ao} = unit stator phase current

e_{ao} = unit stator phase voltage

i_{do} = unit stator direct axis current

e_{do} = unit stator direct axis voltage

I_{ndo} = unit rotor circuit current on the direct axis

ψ_{a1} = phase flux linkages due to stator currents alone

ψ_{a2} = phase flux linkages due to rotor currents alone

Ψ_{nd}, Ψ_{nq} = rotor flux linkages with any direct or quadrature axis rotor circuit respectively

ψ_d, ψ_q = stator flux linkages with equivalent direct and quadrature axis coils respectively

ψ_{ao} = unit phase flux linkages

ψ_{do} = unit direct axis stator flux linkages

Ψ_{ndo} = unit flux linkages for any rotor circuit on the direct axis

No Discussion

Potier Reactance for Salient-Pole Synchronous Machines

SAAD L. MIKHAIL
ASSOCIATE AIEE

IN 1900, Potier presented an interesting paper,[1] in which he explained that the zero power-factor characteristic is displaced from the no-load characteristic vertically by an amount equal to λi and horizontally by an amount equal to αi, where i is the armature current, α is a coefficient of equivalence between the armature and field ampere turns, and where λ is a coefficient dependent on magnetic leakages. It is this λ that is known as Potier reactance and is determined by using the no-load magnetization curve and the zero power-factor (over-excited) magnetization curve.[2,3,4]

Potier reactance is easy to determine experimentally, it is useful in calculating the excitation required under load, and a thorough understanding of its nature is helpful in the analysis of the saturated synchronous machine, not only under steady-state conditions,[5,10] but also under transient conditions.[6,7]

Although Potier only said that the coefficient λ is dependent on magnetic leakages, it was recognized that Potier reactance is greater than the armature leakage reactance by an amount due to the change of field-leakage under direct-axis steady-state conditions. The change of field-leakage under direct-axis loading has been treated in previous articles.[3,4,6,9,10] Since it also is known that the direct-axis transient reactance is greater than the armature leakage reactance by an amount dependent upon the field-leakage,[11,12] it was natural to try to correlate Potier reactance, direct-axis transient reactance, and armature leakage reactance. Only empirical formulas for this correlation exist.[5,8] It is the object of this paper, to present a systematic treatment of the change of field-leakage under a direct-axis steady-state load, and to derive an expression for Potier reactance which is valid under certain assumptions and which can be obtained from design data. Since field-leakage in nonsalient-pole machines is generally small, the treatment is confined to salient-pole machines.

The per-unit system will be used and the following assumptions will be made:

Assumptions

1. The effect of the change of waveform of the flux due to a direct-axis load on the excitation requirement will be neglected.
2. The flux in the air-gap will be assumed the same as that effective in producing saturation in the armature.
3. The effect of saturation of the pole tips on the field-leakage will be neglected when the machine is at no-load or carrying a direct-axis steady-state load.
4. As far as saturation caused by the field-leakage in the pole body or as far as its linkages with the field windings are concerned, the actual field-leakage will be replaced by an equivalent field-leakage passing only between pole tips.
5. Referring to Figure 5, if the machine is carrying a direct-axis demagnetizing current, and if k is the point whose abscissa is equal to the field current minus the demagnetizing armature ampere turns, and whose ordinate is the voltage behind leakage reactance, and if s is the point of intersection of the no-load total characteristic with the curve drawn from k horizontally parallel to the air-gap plus armature characteristic, the chord ks will be assumed to have the same slope as the air-gap plus armature characteristic at the voltage behind Potier reactance. Also the no-load total characteristic will be assumed a straight line between s and the voltage behind Potier reactance.

The Magnetic Circuit of the Machine At No-Load

According to assumptions 2, 3, and 4, the magnetic circuit of the machine at no-load can be represented by the circuit of Figure 1, where:

ϕ_a = flux in the air-gap and the armature
R_a = reluctance of the air-gap and armature; its value varies with saturation
ϕ_l = equivalent leakage flux between pole tips
R_l = equivalent reluctance between pole tips and its value is assumed to be constant
ϕ_p = sum of the armature flux and the equivalent field-leakage flux, and will be called the equivalent pole flux or simply the pole flux
R_p = reluctance of the pole and its value varies with saturation

Equivalent Circuit Under Transient Conditions

For an unsaturated synchronous machine under direct-axis transient conditions, it has been shown[11,12] that the circuit of Figure 2, is a possible equivalent circuit where:

X_l = armature leakage reactance
X_{ad} = unsaturated direct-axis armature reaction reactance
X_f = field leakage reactance
X_f = field leakage when a current equal to $1X_{ad}$ flows in the field

Hence

$$X_f = \frac{X_{ad}}{R_l} \tag{1}$$

The unsaturated direct-axis synchronous reactance X_d' is the reactance between the two terminals a and b, when terminals c and d are short circuited, that is

Paper 50-39, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 20, 1949; made available for printing December 7, 1949.

SAAD L. MIKHAIL is Assistant Lecturer with Farouk 1 University, Alexandria, Egypt, and now is doing postgraduate work at Harvard University, Cambridge, Mass.

Figure 1. Representation of the magnetic circuit of the synchronous machine at no-load

$$X_d' = X_l + \frac{X_{ad}X_f}{X_{ad}+X_f} \tag{2}$$

or

$$X_f = \frac{X_{ad}(X_d'-X_l)}{X_{ad}-(X_d'-X_l)} \tag{3}$$

No-Load Relations

If M_{AA} is the magnetic potential across the air-gap and the armature, and if the subscript "o" indicates no-load conditions corresponding to a flux ϕ_a in the armature, the following relations become evident from Figure 1

$$M_{AA_o} = \phi_a R_a \tag{4}$$

Hence the no-load field-leakage is given by

$$\phi_{l_o} = \frac{M_{AA_o}}{R_l} = \frac{\phi_a R_a}{R_l} \tag{5}$$

And the pole flux is given by

$$\phi_{p_o} = \phi_a + \phi_{l_o} \tag{6}$$

And the no-load field current is given by

$$I_o = \phi_a R_a + \phi_{p_o} R_p \tag{7}$$

Direct-Axis Demagnetizing Load

When the armature is carrying a steady-state direct-axis demagnetizing current i, and when the armature flux is the same as at no-load, equal to ϕ_a, the main magnetic circuit of the machine can be represented by the circuit of Figure 3, where iX_{ad} is the counter ampere-turns of the armature.

From Figure 3, the following relations can be derived

$$M_{AA} = iX_{ad} + \phi_a R_a \tag{8}$$

The field-leakage is thus given by

$$\phi_l = \frac{M_{AA}}{R_l} = \frac{iX_{ad}}{R_l} + \frac{\phi_a R_a}{R_l} \tag{9}$$

Substituting equations 1 and 5 in equation 9, there is

$$\phi_l = iX_f + \phi_{l_o} \tag{10}$$

Also the pole flux is given by

$$\phi_p = \phi_a + \phi_l = \phi_a + \phi_{l_o} + iX_f \tag{11}$$

Substituting equation 6 in equation 11, there is

$$\phi_p = \phi_{p_o} + iX_f \tag{12}$$

Applying Kirchoff's second law to the outer circuit of Figure 3, there is

$$I - iX_{ad} = \phi_a R_a + \phi_p R_p \tag{13}$$

where I is the field current under load.

Substituting equation 12 in equation 13, there is

$$\begin{aligned} I - iX_{ad} &= \phi_a R_a + (\phi_{p_o} + iX_f)R_p \\ &= (\phi_a R_a + \phi_{p_o} R_p) + iX_f R_p \end{aligned} \tag{14}$$

Substituting equation 7 in equation 14, there is

$$I - iX_{ad} = I_o + iX_f R_p \tag{15}$$

Referring to Figure 4(A), e_t is the terminal voltage, $e_i = \phi_a$ is the flux in the armature or the voltage behind leakage reactance, $hj = I_o$. If to hj is added $iX_f R_p$ and iX_{ad}, the result will be equal to the necessary excitation under load. In Figure 4(B) is shown the magnetization curve of the poles alone, $0_1m = \phi_a$, ml is taken equal to ϕ_{l_o}, thus n represents the no-load saturation of the poles corresponding to an armature flux of ϕ_a. If lq is taken equal to iX_f, then np' represents $iX_f R_p$. Hence, taking $jk = np'$, then $kr = iX_{ad}$ thus $hr = 0r_1$ will represent the field current under the considered load, and r_2 whose abscissa is equal to $0r_1$ and whose ordinate is equal to e_t, will represent a point on the zero power-factor (over-excited) characteristic. $0ut$ is the magnetization curve of air-gap plus armature, the curve ks is drawn from k horizontally parallel to $0ut$, till it intersects the no-load characteristic in s. s has an ordinate $= e_i + ss'$ where

$$ss' = iX_{f_1} \tag{16}$$

Figure 2. An equivalent circuit of the unsaturated synchronous machine under direct-axis transient conditions

Figure 3. Representation of the main magnetic circuit of the synchronous machine under direct-axis demagnetizing steady-state load

The foregoing equation is the defining relation for X_{f_1}, which now will be evaluated

$uj = ls$ and $np' = jk$

Hence

$uk = ts = qp$

Since $st = qp$, hence when the machine is operating at no-load, s must represent a point where the flux in the poles is equal to

$$\phi_a + \phi_{l_o} + iX_f \tag{17}$$

The flux in the armature at point s is equal to

$$0f = \phi_a + iX_{f_1} \tag{18}$$

And the equivalent field-leakage is equal to

$$\begin{aligned} \frac{tf}{R_l} &= \frac{uk + s'k}{R_l} \\ &= \phi_{l_o} + \frac{\alpha}{R_l} iX_{f_1} \end{aligned} \tag{19}$$

Where α is the reciprocal of the slope of the air-gap plus armature characteristic at the voltage behind Potier reactance, which is taken equal to the reciprocal of the slope of the chord ks by assumption 5.

Substituting equation 1 in equation 19, the equivalent field-leakage at point s is equal to

$$\phi_{l_o} + \frac{\alpha}{X_{ad}} X_f iX_{f_1} \tag{20}$$

Adding equations 18 and 20, the pole flux at point s is equal to

$$\phi_a + \phi_{l_o} + \left(1 + \frac{\alpha X_f}{X_{ad}}\right) iX_{f_1} \tag{21}$$

Equating equations 17 and 21, there is

$$X_{f_1} = \frac{X_f}{1+\alpha X_f/X_{ad}} \tag{22}$$

or

$$\frac{1}{X_{f_1}} = \frac{1}{X_f} + \frac{1}{X_{ad}/\alpha} \tag{23}$$

Potier Reactance

Referring to Figure 5, Potier reactance is determined[2,3,4] by taking $r_2a = iX_d$, where X_d is the unsaturated direct-axis synchronous reactance, then drawing ac parallel to the air-gap line, till it intersects the no-load characteristic in c, then if X_p is the Potier reactance, there is

$$cc_1 = iX_p \tag{24}$$

It is obvious that ac passes by k and that

$$c_1c_2 = iX_l \tag{25}$$

It remains then to determine

$$cc_1 = iX_{fp} \tag{26}$$

Referring to assumption 5, and letting β be the reciprocal of the slope of the no-load total characteristic at the voltage behind Potier reactance, there is

$$ks' = kc_1 + c_1s' \tag{27}$$

or

$$\alpha i X_{f_1} = iX_{fp} + \beta(X_{f_1} - X_{fp})i \tag{28}$$

Thus

$$X_{fp} = \frac{\alpha-\beta}{1-\beta} X_{f_1} \tag{29}$$

From equations 22 and 29, there is

$$X_{fp} = \frac{\alpha-\beta}{1-\beta}\frac{X_f}{1+\alpha X_f/X_{ad}} \tag{30}$$

Substituting equation 3 in equation 30, there is

$$X_{fp} = \frac{\alpha-\beta}{1-\beta} \times \frac{X_{ad}(X_d'-X_l)/[X_{ad}-(X_d'-X_l)]}{1+\alpha(X_d'-X_l)/[X_{ad}-(X_d'-X_l)]} \tag{31}$$

Potier reactance is given by

$$X_p = X_l + X_{fp} \tag{32}$$

Substituting equation 31 in equation 32, there is

$$X_p = X_l + \frac{\alpha-\beta}{1-\beta} \times \frac{X_{ad}(X_d'-X_l)/[X_{ad}-(X_d'-X_l)]}{1+\alpha(X_d'-X_l)/[X_{ad}-(X_d'-X_l)]} \tag{33}$$

Equation 33 gives an expression that enables the calculation of Potier reactance from design data. All the quantities involved can be determined from design data.[13]

If all the saturation is in the poles, $\alpha = 1$ and thus $X_p = X_d'$. If all the saturation is in the armature, $\alpha = \beta$ and thus $X_p = X_l$.

It is obvious that the above equation, gives the variation of Potier reactance with the voltage behind Potier reactance. If its variation with the terminal voltage is required, it can be obtained afterwards by reducing the voltage co-ordinate of every point by an amount equal to iX_p, where X_p is the value of Potier reactance at the point considered.

Nomenclature

All quantities are in per-unit

X_d = unsaturated direct-axis synchronous reactance
X_{ad} = unsaturated direct-axis armature reaction reactance
X_l = armature leakage reactance
X_d' = unsaturated direct-axis transient reactance
X_f = field leakage reactance
X_{fp} = excess of Potier reactance over armature leakage reactance
X_p = potier reactance
X_{f_1} = defined by equation 16 and Figure 4

Basic Theory Underlying Bell System Facilities Capacity Tables

A. L. GRACEY
NONMEMBER AIEE

ONE OF the principal tasks of the telephone traffic engineer is to determine the quantities of telephone equipment required for adequately and economically handling the traffic offered by telephone users. It is a complex problem, involving forecasts of the volumes and distribution of traffic originating and terminating in each central office of an exchange area, and detailed consideration of each of the components of the various switching systems used in the central offices. For example, the 1,750,000 telephones in the combined Manhattan and Bronx Boroughs in New York are served by 125 central offices; these are interconnected, directly or via intermediate switching centers, by upwards of 9,000 groups of trunks, varying in size from one or two up to a hundred or more, and totaling nearly a quarter-million. Each group must be made adequate for the load it is to carry, and must be readjusted as the distribution of traffic changes. Performing various functions within a typical modern central office are some 40 major groups of equipment units whose proper types and quantities must be specified. All these quantities should be in economic balance in order to meet the objective of minimum cost combined with satisfactory service to the user.

Discussion of the many considerations involved in the layout of a switching network adequate for present needs and flexible for future change is beyond the scope of the present paper. Rather, it deals with the specific problems of determining sizes of trunk groups and quantities of various components of dial central office equipment by the methods currently used in the Bell System. Examples are given, with illustrative tables. Enough of the probability theory underlying the tables is given to bring out the assumptions made to fit or approximate the various service conditions.

Among the basic formulas used are: the binomial, Poisson, Erlang B and C, and Pollaczek-Crommelin. Their application to the principal types of facilities capacity tables in the Bell System is discussed in this paper.

Basic Factors of Telephone Traffic

The commodity with which the telephone business principally is concerned is the telephone call. Calls are made by individual customers as they fit into the living habits or into the conduct of the business of each. In a unit such as the central office, the aggregate of customers' calls follows a varying pattern throughout the day, and facilities must be sufficient in quantity to care satisfactorily for the period of maximum demand, usually termed the busy hour. It is the responsibility of the traffic engineer to see that these are so provided throughout the channels of intercommunication that the grade of service shall be satisfactory to the customer. This is to say that on customer-dialed calls there should be a reasonable minimum percentage of unsuccessful attempts to reach called telephones because of momentary unavailability of switching paths, or that on operator-handled calls for telephones at greater distances the average delay should not be unreasonable.

Basic factors involved in the provision of facilities are: quantities of originating calls, call holding times, numbers of trunks or facilities, and grade of service.

The product of the first two factors is "offered load." It denotes the amount of time that a quantity of calls desires the use of facilities and usually is expressed in terms of hundred call-seconds per hour (ccs) or call-minutes per hour (min.). In European practice a load which engages one trunk completely for an hour is known as an erlang. Since there are 36 hundred call-seconds in an hour, an erlang is equal to 36 ccs or 60 min. Load in erlangs, or average simultaneous offered calls, divided by the number of trunks provided is the trunk efficiency; this value multiplied by 100 is the per cent occupancy. For a predicted load submitted to a group of trunks an appropriate grade of service is selected, and from the proper capacity table the required number of trunks is found. Capacity tables relate the three variable factors of offered load, numbers of facilities, and grade of service; they represent, for a specified number of facilities and grade of service, the load in ccs that can be handled in the busy hour.

It has been found that the laws of probability can be adapted to express conveniently the relationship among the three factors. Based on these laws, there have been developed over the years, by many people, formulas which have proved satisfactory for the derivation of suitable capacity tables.

Formulas used comprehend the characteristics of telephone calls as well as the physical relationship of call sources and communication channels. Among call characteristics are: distribution of calls placed by customers, customer calling rate, call holding time variation, and customer or operator behavior upon encountering busy facilities.

Paper 50-40, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted October 26, 1949; made available for printing December 1, 1949.

Grateful acknowledgment is made to R. I. Wilkinson of the Bell Telephone Laboratories for permission to use selected material from his unpublished notes on Theory of Probability Applied to Telephone Traffic Problems.

Basic Factor Characteristics

Quantities of calls are estimated from prediction of future customer station growth and calling rates. These predictions are influenced by historical data, by knowledge of changing character of the community, by planned changes in office boundaries, by assignment practices among the equipment units in a wire center, or by proposed rate changes.

Elapsed time during which a call occupies facilities is called the holding time. On a call between customers this consists principally of the conversation time plus relatively small intervals required by the equipment to make completion and for the called customer to answer. Holding times for local calls, those within a base rate exchange area, are found to vary according to an exponential law. This is discussed later under formulas. Intertoll calls, those over much longer distances and bearing toll charges, are influenced by other factors such as the length of connection, charge per call, and overtime rate. Their holding times do not appear to follow a simple exponential law.

Holding time of a sender (which stores customers' dial pulses), required only long enough to perform its function in advancing a call, is much shorter than for trunks. While the holding time varies somewhat between calls, the behavior is such that it often is considered constant in nature.

Numbers of trunks in the fixed relationship among the three basic factors of a capacity table vary depending upon the accessibility of trunks to call sources. Ideally, every call source would have complete access to every channel available for completing a call. Economic and physical considerations in the design of dial equipment are such that this is not always true. Any limitation of access adversely affects the relationship of the basic factors. Variations in this condition are illustrated later.

Grade of service may be described in terms either of the frequency with which channels are found unavailable to offered calls or of the average delay encountered. When the call is dialed by one customer to reach another over interlocal trunks in the same city, the trunks or other connecting links ordinarily are provided on such a basis that, on the average, they are found all busy but a small percentage of the time. Grade of service then is expressed in terms of the number of times per thousand calls that all channels are found busy.

Intertoll trunks, since they interconnect cities often widely separated, are more expensive than interlocal trunks and hence usually are provided on a less liberal basis. Grade of service therefore is expressed in terms of the average delay on all calls. This criterion implies that the call is operator-handled. If there is a short delay, the customer may be held at the telephone; if it proves too great, he may be allowed to hang up whereupon the operator follows the situation and secures a trunk as soon as one is available.

Principal Formulas and Illustrative Capacity Tables

General Assumptions in Regard to Offered Traffic

Obviously the distribution of calls placed by customers has an important bearing on the number of channels required for completion; that is, they might be placed at uniform intervals, spasmodically, or at random. It is customary to assume that each customer originates his calls quite at random during his idle time and independently of all other customers. Although this latter assumption is not strictly true, for example, when two customers are talking there is clearly a restriction on their ability to originate calls independently, in general the correlation appears to be neglectible. For periods as long as the busy hour the random placement of calls usually seems to be quite well realized.

Each customer over a long period of time originates the same total call-seconds of load as every other customer; in other words, p, the probability that at any random moment any particular customer will be using his telephone, is assumed constant. This, of course, decidedly is not the case. Customer calling rates vary widely although the average calling rate of all customers is used in engineering. It can be shown in most cases, however, that the nonuniformity in offered load among customers results in slightly better service than that predicted by formulas based on the uniform load assumption.

Holding times for the cases of delayed call situations are assumed either to be constant or to vary exponentially. (Other formulas, for "lost calls cleared" and "held", are derivable without restriction as to the form of holding time distribution.) The exponential law has been found to describe remarkably well the distribution of local call conversation times.[1,2] Its formula is

$$P(\geq t) = \epsilon^{-t/t(\text{avg})} \qquad (1)$$

where

$P(\geq t)$ = the probability that any randomly selected holding time will equal or exceed a length t,
ϵ = the Naperian logarithmic base, 2.718,
$t(\text{avg})$ = the average holding time of all customers' calls.

Disposition of calls which do not find a trunk immediately available depends on a number of things. When such a call is dialed by a customer, the selecting mechanism ordinarily indicates to him that no path is available. The call then is lost from the system. However, in the majority of cases it is known that subsequent attempts are made to complete the call.[3] These attempts are not made in a random manner.

If, when a customer first lifts his receiver to make a call, a channel in the first step of the train of connection is not available, he usually waits until one becomes so. When calls are handled by operators and trunks are selected by them, the disposition of a call depends on the operating practice or upon the customer's instructions; he may be held at the telephone while repeated attempts are made to find an idle trunk or he may be given an immediate busy report.

From the foregoing it is seen that behavior varies when channels are not immediately available to receive a call.

In fact, it varies between two extremes. On the one hand, some calls, upon not finding a path immediately, disappear from the system not to return again in the same period, say the busy hour. This assumption, lost calls cleared, is the basis of a formula for obtaining the probability of loss known as the Erlang B formula which is discussed later. A lost call is one which, when offered to a group of trunks, finds all trunks busy regardless of what happens to it thereafter. On the other hand, some calls, upon finding no channel available, wait in suspense until one becomes idle at which time the channel is seized and held for the full holding time. This assumption, "lost calls delayed," is the basis of another formula for obtaining the probability of loss. It is known as the Erlang C formula.

Between these extremes is an intermediate assumption, "lost calls held", upon which are based the binomial and the Poisson formulas. The physical equivalent of these expressions for the disposition of lost calls sometimes has been described as follows: an offered call, upon finding no idle trunk, waits for an interval of time exactly equal to its holding time and then disappears from the system; if a trunk becomes idle while the call is waiting, the trunk is seized and occupied for the portion of the holding time then remaining. This behavior is

known as the lost-calls-held assumption to distinguish it from other assumptions used in other formulas.

Regarding what happens to lost calls, it readily is seen that the three assumptions (lost calls cleared, held, and delayed) have differing influences on the theoretical probability in each case of calls being lost. Where lost calls are cleared from the system, they do not occupy trunk time. For a given offered load this probability of lost calls is therefore lowest among the three assumptions. Where lost calls are held, they occupy some trunk time; if the probability of loss is low, they occupy nearly the full holding time. Probability of loss under this assumption is higher than for lost calls cleared. Where lost calls are delayed, they occupy trunks for the full holding time, and the probability of loss is thus highest of the three assumptions.

As stated earlier, telephone traffic is varied in its characteristics and does not behave in ways which are in all respects precisely like the basic assumptions underlying any of the various probability formulas; very often a system actually operates somewhere between the limiting cases. Although no systems present or contemplated perform the peculiar transfer of calls waiting to calls talking that is comprehended by the lost-calls-held assumption, the net result appears to be reasonably descriptive of customers' performance generally. Some, upon meeting an all-paths-busy signal, hang up and do not return; others wait a considerable interval and try again; and still others make repeated attempts at very short intervals. In the Bell System, therefore, formulas based on the lost-calls-held assumption have been adopted as the foundation for many of its engineering tables where spheres of use require that criterion of measurement.

Binomial Formula

The basic formula, or some variation of it, which underlies the greatest number of capacity tables used in the Bell System, is the binomial. As applied to a group of trunks, all of which are accessible to all sources, it expresses the probability of loss where calls are offered to the group with number of customers, probability of customers talking and wishing to talk, and number of available trunks known. Probability of loss is a term used to denote the probability of finding all trunks busy. The formula follows

$$P(c,n,p)=\sum_{x=c}^{x=n}\binom{n}{x}p^x(1-p)^{n-x} \qquad (2)$$

where

P = the probability that over some period, say an hour, any customer when placing his call will find all trunks busy.

c = the number of trunks available to receive calls.

$n+1$ = the total number of customers who have access to all trunks in the group.

p = the probability that at a random instant during the hour any particular customer is talking or wishes to talk. (The per cent occupied time of each customer or source is $100p$.)

Σ = the instruction to add together all solutions for the expression following it for values of x ranging from c to n in steps of one.

$\binom{n}{x}$ = a conventional way of indicating the number of combinations of n things taken x at a time and equals $n!/x!(n-x)!$

Illustrative Table

It is noted in the binomial formula that the number of sources which originate calls influences the probability of loss. In the case of switches in the step-by-step dial system, the relation between the number of traffic sources and trunk paths is such that the influence of number of traffic sources on probability of loss is recognized in the content of capacity tables. Here, the binomial formula is employed as a basis for relating loads and service. Capacity Table I illustrates load values selected from a typical step-by-step trunk table.

Table I. Capacity Table

Step-by-Step Graded Multiple Trunks; Hundred Call-Seconds (ccs); 10 Terminal Assignment; Table 10 Service

Trunks	Selectors Per Subgroup 320	240	160	120	80
11	166	168	170	172	176
15	240	245	246	249	254
25	426	430	434	444	465
35	602	614	626	650	692

Capacities in this as in subsequent table illustrations are, unless otherwise noted, in ccs. Table I is for step-by-step graded multiple groups where a given call has access to ten trunks only (10-terminal assignment). Values are such that when groups are loaded to the indicated capacity, ten calls in a thousand find all trunks busy (Table 10 service). Table numbers similarly used in later illustrations have the same significance; that is, the number indicates the number of calls per thousand offered which can be expected to find all trunks busy. Numbers of selectors per subgroup constitute the numbers of traffic sources from which calls are offered to the group. Figure 1 illustrates the equipment arrangement for 80 selectors and 15 trunks.

Figure 1. Graded multiple arrangement

With the graded multiple arrangement of trunks, all traffic sources do not have access to all trunks. Load values in Table I are modified to reflect the effect of this limitation. The arrangement is discussed later under Miscellaneous Modifications.

Poisson Formula

In the binomial formula, as the number of sources $(n+1)$ which supplies a given traffic load $[(n+1)p=a]$ increases, the probability of loss on c trunks also increases and approaches a limiting value as n becomes very large and p becomes correspondingly small. Under this condition, the formula can be expressed in different form. It is known as Poisson's Exponential Binomial Limit but usually is referred to simply as the Poisson.[4,5] The formula follows

$$P(c,a)=\sum_{x=c}^{\infty}\frac{a^x e^{-a}}{x!} \qquad (3)$$

where

P and c have the same significance as in the binomial formula.

a = the average simultaneous calls offered during the hour. It is equal in value to the product of the quantities n and p in the binomial. This average multiplied by 36 is the offered load in ccs.

The following statement serves to indicate roughly the field of application for the Poisson as compared with the binomial formula: when the number of sources is greater than eight times the number of trunks serving them, for commonly used grades of service ($P=0.02$ and smaller), the Poisson specifies fewer than five per cent excess trunks over the binomial formula.

With the exception of the step-by-step groups previously cited, the Poisson generally is used as the basis of capacity tables for most other types of facilities where the service criterion is in terms of probability of loss. This can be done because the number of traffic sources with respect to the number of trunks is such that the Poisson gives a reasonable approximation of the true binomial values.

Illustrative Table

Capacity Table II illustrates load values selected from tables for trunk groups in which all sources have access to all trunks. They are calculated directly from the Poisson formula. It is noted

Table II. Capacity Table

Ungraded Multiple Trunks, Hundred Call-Seconds (ccs)

Trunks	Service Table 1	Service Table 10	Service Table 20
40	837	964	1,012
50	1,115	1,261	1,317
60	1,400	1,565	1,627
80	1,986	2,184	2,258

that the capacity of an 80-trunk group is more than double that of a 40-trunk group for the same grade of service, which is to say that the larger group is more efficient. This increase in efficiency with increase in number of trunks per group is more marked in the lower ranges of group size.

Figure 2 demonstrates this characteristic in group sizes from 1 to 100 for Poisson probabilities of loss of 0.001 and 0.01 (Tables 1 and 10 service respectively). Trunk efficiency is the term a/c from Poisson formula values. As stated earlier, when multiplied by 100 it also is the per cent occupancy.

Erlang B Formula

When the probability of lost calls is low, there is little difference in trunk requirement among the several assumptions regarding lost call behavior. Although the Poisson generally is the basis for most Bell System capacity tables, there are types of problems for which it is not suited. Typical are those involving amount of switch hunt, amount of wear on terminals, and distribution of load over terminals. For these the Erlang B formula,[5,6] based on the lost-calls-cleared assumption, has been found suitable. It follows

$$B(c,a) = \frac{a^c/c!}{1+a+a^2/2!+a^3/3!+\ldots\ldots+a^c/c!} \qquad (4)$$

where

B = the probability that all trunks will be found busy. In this formula, B implies the lost-calls-cleared assumption as P in the binomial and Poisson implies the lost calls held.

c = the number of trunks available.

a = the average simultaneous calls offered during the hour.

This formula also is used widely in the determination of trunk requirements for

Figure 2. Load carried per trunk at a constant probability of loss

alternate routing. An alternate route arrangement of trunks from a central office is simply a variation of graded multiple, the principles of which are described later.

Alternate routing is a device, used at present only in crossbar-type dial offices, for improving interoffice trunk efficiency. Direct trunk groups between central offices are strongly cut back leaving the earlier choice, and hence more heavily loaded, trunks in service. The average efficiency of these direct trunks thus is increased materially over the former average for all interoffice trunks. The overflow calls from two or more such direct routes then are combined and sent via an alternate route to a tandem or intermediate switching center. Here similar alternate routed calls from other originating offices are sorted out and those to a specific terminating point recombined and sent over tandem completing trunks groups to the various destinations. By combining in this way the overflow traffic from a considerable number of direct routes, a sufficient load to (and from) tandem may be accumulated so that as suggested by Figure 2, a relatively efficient trunk group size can be attained for all alternate routes. Thus the over-all efficiency of the general trunk system is raised considerably above that obtainable with only direct interoffice trunking.

Illustrative Table

Table III is a portion of a table derived directly from the Erlang B formula, which

Table III. Alternate Routing Trunk Tables

CCS Carried by and Overflowing From Each Trunk Shown in Column Headings

CCS Offered	Trunk Number 10 Carried	10 Overflowing	11 Carried	11 Overflowing	12 Carried	12 Overflowing
300	16	41	13	28	10	18
305	16	44	14	30	10	20
310	17	46	14	32	10	22
315	18	49	14	35	11	24

is used in calculating alternate route trunk requirements. The significance of this table is explained by the following example:

If 300 ccs per hour are offered to ten trunks, the tenth trunk carries 16 ccs and 41 ccs overflow beyond it. This assumes that load always is offered to the trunks of a group in turn, beginning with the lowest numbered. Where this is not so, the significance of 16 in the example is expressed differently: the addition of a tenth trunk to a 9-trunk group results in the addition of 16 ccs to the load carried on the group.

Finding the proper combination of direct and alternate route trunks consists of determining for each outgoing traffic item the most economical number of direct trunks based on the cost ratios of alternate to direct channels. The efficiency of the alternate channel in ccs per trunk per hour, divided by the above ratio, is the load in ccs which should be equaled or exceeded by all trunks in the direct group. Alternate route group size is determined for the composite of the overflow from direct trunks. Although not rigorously correct, it is the usual practice to use the composite load to enter a Poisson table to determine the number of common paths required.

Pollaczek-Crommelin Formula

Where the probability of lost calls is not small and where operators handle the calls for customers, such as in the case of intertoll calls, the more significant measure of grade of service is average delay on all calls. The Pollaczek-Crommelin formula[4] best expresses the relation between load and grade of service for this class of traffic. It is based on assumptions of constant holding time and lost calls delayed.

Illustrative Table

Capacity Table IV is a portion of a table derived directly from the foregoing formula.[7] In this table the number 30 in column headings signifies that during the busy hour the average delay for service on all calls is 30 seconds. The capacity of 40 trunks, for example, when trunk holding times range from 5.8 to 7.2 minutes, is 2,246 call minutes per hour. Average delay on all calls offered throughout a day is six seconds. Capacity could be expressed in ccs by multiplying by 0.6.

Miscellaneous Modifications and Illustrative Capacity Tables

Graded Multiple

Graded multiple is an arrangement of trunks wherein subdivisions of the total number of calls offered to a group are pre-

sented first to subgroups of trunks individual to them; upon failure to find an idle trunk, the calls are next presented to one or more subgroups of trunks which are accessible to some or all of the other subdivisions of calls. A simple, symmetrical graded arrangement such as may be found in a step-by-step type dial office is illustrated in Figure 1.

In this group of 15 trunks, each subgroup of 40 selectors has access first to five trunks individual to it and thence to five common trunks accessible to the entire 80 selectors. Where it is not possible to use such an arrangement it would be necessary to provide individual subgroups, each not greater than ten trunks. The graded group is more efficient than an individual subgroup of ten trunks because the common trunks can team in giving access to calls that overflow the individual trunks thereby making them more efficient than tail-end trunks in an individual group. This subject is covered at length in an article by R. I. Wilkinson.[8]

Capacity of a graded arrangement is calculated by increasing the efficiency per trunk of a simple group equal in size to the access, by the theoretical percentage of gain (graded multiple gain) for that arrangement and multiplying by the number of trunks in the graded multiple group. This type of arrangement is used in dial offices where economic design considerations and a standard fixed switch size limit the access.

Illustrative Table

Capacity Table V shows selected values from a table for graded multiple groups in a panel-type dial office. Traffic sources here are sufficiently great in number so the table is based on the Poisson formula and values are increased by the graded multiple gain for each group size. Access for any one call is 20 trunks.

Call Count Correction

Occasionally, the count of dialed calls as used in engineering dial facilities does not include all uses of each facility, such as in the case of a customer sender in a panel or Number 1 type crossbar office. Here, the count of calls ordinarily includes only those where at least a central office code is dialed by the customer. However, customer senders function also when a code is not completely dialed or even when a receiver is lifted and replaced without any dialing.

In order to simplify engineering it is found expedient to base customer sender usage on the usual count of dialed calls and appropriate holding times. The senders required for the calculated load then are secured from a capacity table into which is incorporated an empirical allowance for sender usage not included in the count of calls. This allowance is based on average customer behavior in all dial offices.

Illustrative Table

Selected values from a table for panel-dial customer senders are shown in Capacity Table VI. They contain an allowance of 23 per cent for calls not included in the regular count; as actually derived they are based on Poisson formula values divided by 1.23. There is full accessibility between call sources and senders.

Primary-Secondary Arrangements

In dial practice there frequently are situations where some variety of primary-secondary arrangement is used in order to associate traffic sources with trunk paths. Such an arrangement is less efficient than one wherein all sources have complete access to all paths. It usually is very much less expensive, however. It has been found empirically in numerous cases of practical interest that the efficiency is about 5 per cent less than where there is full access. This is to say, that with full access and a requirement of 38 trunks, for example, there would be required with a primary-secondary arrangement 40 trunks for the same load and grade of service.

Figure 3 is a schematic drawing of a set of crossbar switches showing the method of interconnecting 100 sources with 100 paths. Ten primary and ten secondary switches, each set numbered zero to nine, have ten vertical and ten horizontal terminals. Figure 3 indicates the pattern for connecting the horizontals. Switches and horizontal terminals one to eight inclusive are not shown.

Illustrative Table

Capacity Table VII is a portion of a crossbar customer sender table. Values are based on the Poisson formula, modified for a call count correction of 23 per cent as in Table VI and also by a 5 per cent correction for reduction in efficiency due to the use of a primary-secondary arrangement. Senders are accessible to all calls.

Random Slip Multiple

Where design limitations are such that it is not feasible to give all traffic sources access to all trunk paths, another arrange-

Figure 3. Crossbar primary-secondary arrangement

80	1,670

ment is used where the equipment lends itself to such treatment. This is known as a random slip multiple distribution of load to trunks. It is a limited access arrangement wherein, if applied to senders, for example, the choice of the particular t senders to be available to one of a number of equal volumes of offered load is made in a random fashion such that, as far as possible, when x calls are in progress they will be as likely to be connected with any x senders as any other x senders out of a total of T.

Figure 4 illustrates a simple random slip multiple arrangement. Five equally loaded subgroups are served by five senders with but four available to any one subgroup.

The formula for probability of loss[9] with this arrangement is

$$P_t = \frac{a^t(T-t)!}{T!}[1-P(T-t,a)]+P(T,a) \qquad (5)$$

where

P_t = the probability of loss
a = the load in average simultaneous calls submitted to T
T = the total number of trunks
t = the number of trunks available to any one call

Figure 4. Random slip multiple arrangement

$P(T-t,a)$ and $P(T,a)$ are the Poisson expressions of loss for load a and for $(T-t)$ and T trunks respectively.

Illustrative Table

Table VIII. Capacity Table

No. 4 Type Crossbar Senders; 40 Sender Access; Table 10 Service

Senders	CCS
40	907
50	1,176
60	1,440
80	2,012

Capacity Table VIII contains selected values from a table for Number 4 type crossbar senders. Values are based on the probability of loss according to the random slip multiple formula. Maximum sender access for any subgroup of load is 40. Table values also have been modified for the effect of the primary-secondary arrangement of crossbar switches previously described.

Conclusion

Capacity tables illustrated by no means include all that are used in the Bell System. They do, however, cover the principal types and exemplify applications of the most used probability formulas, to the engineering of conversation channels and facilities.

Discussion

R. I. Wilkinson (Bell Telephone Laboratories, Inc., New York, N. Y.): In his excellent paper on Bell System facilities capacity tables, Mr. Gracey has suggested that much more work on the traffic carrying capacities of switching systems has been, and is being, done than he has described. This is quite the case. Since the fall of 1905 when E. C. Molina first used the binomial formula as proposed in an historic memorandum of October 22, 1903, by M. C. Rorty (then both with the American Telephone and Telegraph Company), the applications of probability to trunking theory in the Bell System have been many and varied.

Mr. Gracey presented formulas for relating load, size of group, and grade of service for three rather special, though widely-used assumptions as to the disposition of calls failing to obtain immediate service. It may be mentioned that in 1930 we at Bell Laboratories developed what has come to be called the "infinite source generalized trunking formula" which by the insertion of an added parameter, j, permits the calculation of the congestion corresponding to any desired lost calls assumption between the two extremes of "cleared" and "delayed."*

For the most general case of $n+1$ sources each originating on the average m calls per idle time h, where h is the average holding time, the loss expected on a full access group of c paths, will be

$$P = \sum_{x=c}^{n} f(x) = \frac{\displaystyle\sum_{x=c}^{n} \frac{n!}{(n-x)!c!} m^x \frac{(c/j)!}{j^{x-c}(c/j+x-c)!}}{\displaystyle\sum_{x=0}^{c-1} \frac{n!}{(n-x)!x!} m^x + \sum_{x=c}^{n} \frac{n!}{(n-x)!c!} \times \frac{(c/j)!}{m^x j^{x-c}(c/j+x-c)!}}$$

The disposition of delayed calls is regulated by j, and it may readily be shown that

$j=\infty$ corresponds to lost calls cleared
$j=1$ corresponds to lost calls held
$j=0$ corresponds to lost calls delayed

When $n \to \infty$ the congestion equations reduce to the Erlang B, Poisson, and Erlang C, respectively.

Until recently our detailed knowledge of subscriber telephone behavior has been insufficient to warrant more than meager use of j's other than those producing the formulas described by Mr. Gracey. However, we now are engaged in a series of field studies which promise ultimately to allow us to select j-factors more exactly suited to some of the important subscriber-central office situations. These field studies are a part of a considerably more comprehensive program of investigation of subscribers telephone performance.

We also are giving close attention to the operating characteristics of the various types of central offices in use by Bell System Companies. This involves a determination

*The equivalent formula for infinite sources (and using $\delta = h/j$) was derived independently by Dr. Conny Palm.[1] He also gave the formulas for the corresponding distribution of call delays.

of the over-all response of trains of equipment, often with complex interdependencies, to normal traffic loads and to specified degrees of overload. This is being done by means of theoretical analyses, by simulated traffic tests, and through field studies of the system.

By a suitable association of the results of these studies we are obtaining guidance toward the development of the most economical equipment amounts and arrangements, in addition to determining relationships useful for engineering and administrative purposes.

The Number 5 Crossbar Dial Telephone Switching System

F. A. KORN
MEMBER AIEE

JAMES G. FERGUSON
ASSOCIATE AIEE

IN January 1939 a paper was presented to the Institute[1] by F. J. Scudder and J. N. Reynolds of Bell Telephone Laboratories which described a crossbar dial telephone switching system which was just being introduced in the Bell System. Known as the Number 1 Crossbar System, it was designed for large cities where the panel system had been used for almost 20 years. Since then approximately 350 crossbar dial offices of this type, serving nearly 5,500,000 subscriber stations, have been installed in the larger cities throughout the country. During these years improvements have been made in the Number 1 crossbar system to make it more serviceable to the telephone user and to meet the new problems which have arisen.

Bell Telephone Laboratories' engineers have continued their searches for new and better telephone switching systems. One such search was for a dial system which would better meet the telephone switching requirements for areas on the outskirts of metropolitan cities and at the same time care for medium-to-large sized offices in other areas. Work on this problem culminated in the development of the new Number 5 crossbar system, and on July 11, 1948 the first office of this type was placed in service at Media, Pa., a suburb of Philadelphia.

The field of application of this new switching system is more extensive than that of any developed previously. The Number 5 system is capable of operating with all present local, tandem, and toll switching systems of the Bell System and of the independent companies which connect with it. In addition, it can serve as a tandem or toll center switching office where this is advantageous. It can be readily equipped with features for operation as required at toll centers for nationwide operator toll dialing and also for automatic message accounting[2] which permits subscriber dialing to be extended to considerable distances. Number 5 crossbar is designed for operation with as few as four digits in a subscriber number or it can complete calls which require as many as 11 digits, (dialed by operators) three for the national area code,[3] three for the office code, four for the numericals and the last for the station letter of the called number on certain types of party line service.

General Description

The Number 5 crossbar system is like the Number 1 system in that:

1. It is essentially a relay system employing simple forms of relays and relay-type structures for all switching operations. The apparatus consists largely of crossbar switches, multicontact relays, and smaller relays similar to those generally employed in all telephone switching systems. Practically all have double contacts of precious metal to lessen the likelihood of contact failure and to improve transmission. The crossbar switch, multicontact relays, and general purpose relays were described in considerable detail by Scudder and Reynolds.

2. Primary-secondary arrangements of crossbar switches funnel the traffic from lines to trunks and from trunks to lines. Each group of trunks to a connecting office may have from two to several hundred circuits and the switches serve trunk groups economically whether they are large or small.

3. Utmost freedom of action in routing each call is provided by components which transfer all control over switching sequences from the subscriber's dial to circuit elements in the office. The digits dialed are stored in registers and can then be translated into other codes employing one or another pulsing means, not necessarily decimal. This translated information is then sent to the switches selected to give them whatever directions they need in the most suitable forms and at the time they need them.

4. The register, sender, and translator elements are employed for only a short time in each connection, thus small groups of them serve large groups of lines. Each element is brought into a connection for only the interval required to perform its function.

5. Control over practically all switching and pulsing operations is centered in groups of circuit elements called markers. They perform so quickly that a few of them will handle all calls in an office. The crossbar switch lends itself to this fast operation because its contacts stand ready to close in an instant and no time is lost in switch action to hunt for a connection. Since relatively small groups of these control circuits (markers, registers, senders, and so forth) are used over and over again by many other connecting circuits they constitute what is called common control operation.

6. Advantage is taken of secondary benefits from common control including the following:

(a). If all trunks are found busy in the preferred group first selected, the marker may choose an idle trunk in an alternate route.

(b). Each element in the connection tentatively selected for a call is tested, and if a trouble is encountered in the path, the marker makes a second trial and brings into the connection a different group of elements. Usually a different marker is called upon to make the second trial and this serves to minimize the reaction from trouble in the marker itself.

Paper 50-41, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 1, 1949.

F. A. KORN and JAMES G. FERGUSON are both with the Bell Telephone Laboratories, Inc., New York, N. Y.

Figure 1. Basic arrangement of switching plan

Figure 3. Line link and trunk link frames—simplified trunking plan

(c). Since the marker has access to most of the elements in an office it is endowed with the ability to gather information from many sources on the performance of the different parts. It is therefore able automatically to refer to the maintenance force incipient troubles (and their locations) before they react on service.

Number 5 crossbar differs materially from Number 1 in the following:

1. Switching plan.
2. Trunking arrangements.
3. Utilization of new items of apparatus.
4. Equipment design.
5. Circuit operation.
6. Maintenance provisions.

These are described briefly in this order in the sections which follow. The unusual combination of versatility with standardization, the extended use of the common control principle, and the introduction of new maintenance concepts described in these sections endows Number 5 crossbar with important features which are summarized in a concluding section.

Switching Plan

The Number 5 system differs from Number 1 primarily in its switching plan, a simple block diagram of which is shown in Figure 1. Each subscriber line appears on one of the line link frames and all trunk and originating register circuits on trunk link frames. It should be noted that, as in the case of Number 1, the line has but a single appearance on the line link frame and this serves for both originating and terminating calls. Every connection is set up from a trunk or a register to a calling or a called line through crossbar switches on trunk link and on line link frames. The common control equipment which is used to set up the various connections includes the markers, the connectors, the number groups, the senders and registers, and the sender and register links. Once a talking path is established, all control elements are released and only the line link, trunk link, and trunk circuit elements remain in the connection.

Before any talking path is set up, all needed information on calling and called parties is registered in a way which enables a marker in a uniform and flexible manner to call into the connection only those switching, signalling, transmission and supervisory features required for the particular call. On every subscriber call, the calling line, through a connector, engages a marker to connect the calling line temporarily to an originating register through crossbar switches of the line link and trunk link frames after which the connector and marker are released. When all of the needed information on calling and called parties is stored in the originating register, a marker is again engaged for a fraction of a second to establish the talking connection. Knowing both ends of the connection required and with no switching equipment committed, the marker is free to set up any kind of a call with the best combination of elements. If the call is to another subscriber in the same office, the marker connects an idle intraoffice trunk circuit to the calling and called lines.

If the call is to a destination outside the office, the marker recognizes this from the information dialed and proceeds to connect the calling line to a trunk circuit in the proper group. If a sender is needed, the marker connects one of the appropriate type to the trunk circuit through a sender link. Senders receive information from the marker and transmit it in the form of pulses to registers, other senders or directly to switches as required in the systems of the connecting offices. This information may be the called subscriber's numerical digits or it may include office code digits as well. Since senders must be capable of operating with the standard kinds of signaling, four types are available for "dial pulse," "revertive pulse," "multifrequency pulse" and "panel call indicator" operation. Multifrequency pulsing is generally used for signalling between Number 5 offices, to and from Number 4 toll crossbar offices, to Number 1 crossbar and to crossbar tandem offices.[4,5]

If the call is incoming from another office, the incoming trunk circuit associates itself with an incoming register through an incoming register link. The incoming registers receive information from senders, dials, or keysets in the distant offices and pass this information to the markers for establishing the switch-

Figure 2. Crossbar switch

Figure 4. Simplified typical office trunking plan

ing connection either to a called subscriber line in the same office, or to a distant office when through switching of toll or tandem traffic is involved. Incoming registers, like senders, must be capable of operating with the standard kinds of signaling, hence there are "dial pulse," "revertive pulse," "multifrequency pulse" and "B switchboard" registers.

The flexibility afforded by this switching plan can be illustrated by a simple manual switchboard analogy. Imagine a manual operator who has direct access to lines and trunks of every variety in the quantities needed. Over a preliminary connection she is quickly given complete information regarding the nature of each call. Then, knowing all she needs to about both calling and called parties, she dismisses the preliminary connection and establishes the talking path by assembling the proper combination of transmission, signaling, supervisory, and charging circuits required for that connection and connecting that combination between the jack of the calling line or trunk and the jack of the called line or trunk.

Trunking Arrangement

The crossbar switch from which the system derives its name is shown in Figure 2. Since it has been described in detail by Scudder and Reynolds, it will be sufficient to describe it as a co-ordinate arrangement of contacts, giving 10 or 20 sets of contacts on one ordinate access to ten sets on the other. Thus 10 or 20 circuits may have access to ten circuits of a different type. The first 10 or 20 circuits referred to might be trunk circuits and the second ten, registers. The number of trunk circuits which can be given access to the same ten registers may be increased to 40 by adding a second switch with 20 additional trunk circuits connected to its verticals and by interconnecting the horizontal contact multiples of the two switches. By adding switches in this manner, any number of trunk circuits may be given access to the ten registers on the horizontals. This is known as the direct access form of trunking and is used in the Number 5 system for the sender and register link circuits.

To obtain access to a larger number of circuits, two groups of ten switches, known as "primary" and "secondary" are used and these are interconnected in a manner so that any particular line can be connected to any of a total of 100 or 200 outlets by closing contacts on two

Figure 5. Section of typical Number 5 office

Figure 6. Trunk link frame

switches. This type of trunking is used on both the line link and trunk link frames of the Number 5 system. The arrangement of switches on these frames and the junctor interconnections are shown in Figure 3. In the Number 5 system the "line" and "trunk" switches are the primaries and the "junctor" switches are the secondaries.

The basic line link frame of the Number 5 system has a capacity of 290 lines and by the use of 100- and 200-line supplementary bays as many as 690 lines may be assigned to form a line group. A maximum of 40 such line groups (with a maximum of 20,000 directory numbers) can be accommodated by one group of markers not exceeding 12 in number. These numbers are arbitrary design limits and can be increased without changing the system fundamentally if experience indicates a larger capacity to be more desirable. Each line link frame has 100 outlets, known as "junctors," which connect this frame to all trunk link frames—approximately an equal number of junctors connecting to each trunk link frame.

On the line link frame these junctors ap-

Figure 7 (above). Number group frame

Figure 8 (right). Marker

pear on the verticals of the combined line and junctor switches. These are 20-vertical switches on which the horizontal paths are separated between the 10th and 11th verticals so as to provide the equivalent of two 10-vertical switches each having ten horizontal paths. The horizontal paths of one section are directly connected to those of a line switch, thereby providing what is effectively a 30-vertical line switch. Each line on each of these extended line switches has access to the ten "line links" appearing on the horizontals. These ten links are distributed over the ten junctor switches so that each line has access to each of the 100 junctors.

The trunk link frames provide means for connecting the line link frames via their junctors to all of the intraoffice, outgoing, and incoming trunks, as well as to all of the originating registers required for dial tone service. This frame, in addition to having a capacity of 200 junctors to all of the line link frames, has 160 outlets to which trunks and originating registers may be connected. On this frame the junctor switches have their horizontal multiples divided to provide 200 horizontal paths for connecting junctors from all of the line link frames. Each junctor switch provides access between the ten junctors on each of the two half-sections and the ten "trunk links" on the verticals of each section. These 20 links are distributed over the ten trunk switches on the frame, two to each switch. Thus, each junctor has access to any trunk or register.

Figure 9 (left). Typical connector frame

Figure 10 (right). Maintenance center at Media, Pa.

A different arrangement is used at the trunk switches to obtain access to 16 horizontal terminations per switch or 160 per frame. These switches have 6-wire crosspoints on the upper eight horizontal levels so that two 3-wire circuits of the trunks and registers can be accommodated. Two trunk or register appearances, known as *A* and *B*, are connected to each of these levels to provide a total of 16 per switch. The lower two levels, 0 and 1, function as selecting levels and have only three sets of crosspoints arranged so that on level "0" the crosspoints correspond with the left three springs of the crosspoints on the upper levels and on level "1" with the right three springs. In this manner level "0" is used for *A* appearance trunks or registers, and level "1" for the *B* of the 16 that might appear on the switch. In this case the trunk links are not wired to the vertical multiple of these switches, but instead are wired to the individual contact points of both levels 0 and 1. Connection of a trunk link to a trunk or register is made by operating two selecting magnets; one, the selecting magnet corresponding to the trunk or register appearance and the other, either 0 or 1, depending upon whether the trunk or register is associated with the left or right half of the vertical multiple.

Since each trunk link frame provides 200 junctors and each line link frame only 100, there are usually twice as many line link as trunk link frames. The 100 junctors from a line link frame are distributed

Figure 11 (left). Typical functional unit

Figure 13 (right). Section of frame showing method of opening or removing front cover

over the junctor switches of all the trunk link frames in an office. The number of junctors between these frames will vary depending upon the actual number of trunk link frames. There will be at least one junctor, as shown, from each junctor switch on a line link frame to a junctor switch on each trunk link frame, or a minimum of 10 junctor paths between any of these two types of frames. There will be at least 10 junctors between frames, which is the minimum to insure satisfactory call-carrying capacity. When there are more than ten trunk link frames or more than 20 line link frames, a supplementary bay of junctor switches is added to each trunk link frame to increase the number of junctor terminations from 200 to 400. In this case each junctor from a line link frame is connected to two trunk link frames. In order to connect a particular line to a particular trunk, an idle channel consisting of a line link, a junctor, and a trunk link is selected through the switches of these two types of frames. These three elements connect in series as shown in Figure 3.

The arrangement of links and junctors for a line link frame and trunk link frame is shown in Figure 3. Extension of this method of interconnecting for a typical office is shown in simplified form in Figure 4.

New Items of Apparatus

The Number 5 system takes advantage of some ten years of operating experience with the original Number 1 crossbar system and many advances in theory and technique that have resulted from continuous research in telephone switching. As one result, new or improved types of apparatus are used widely. The following are some examples:

1. Relays and switch designs have been improved. These also will have application in other systems.

2. Cold cathode tubes have found a number of new uses, particularly for time delay circuits.

3. Mercury contact relays are used in substantial quantities in some of the critical circuits of the marker. This relay consists of a sealed-in-glass mercury contact switch inserted in an operating coil, the assembly being mounted on a small wafer octal base and housed in a metal-vacuum-tube type of covering. All contact surfaces are covered with a thin film of mercury maintained by capillary action from a base pool. These relays are designed to provide long life with high stability of operation, freedom from open contacts due to dirt, fast operating, and releasing times and permit the switching of high current load when provided with adequate contact protection.

4. A new device known as a "trouble recorder" has been developed for this system. It is engaged when trouble is encountered by the control circuits and automatically records, by perforating a card, essential information which will aid the maintenance forces in locating such troubles.

Figure 12. Originating register

Equipment Design

The primary objective in equipment design for the Number 5 system was to exploit to the fullest extent the flexibility inherent in the switching plan. The second objective was to standardize the arrangements in the fewest patterns with the fewest parts and assemblies for most economical production. In spite of the fact that the two objectives are frequently incompatible, flexibility has been combined with standardization to an unusual degree.

Figure 5 shows a section of a typical Number 5 crossbar central office. As this picture suggests, the equipment arrangements in the new office are generally similar to those in other large crossbar offices. Lines of switch frames 11 feet 6 inches high and about 40 feet long are arranged on one or more floors of the building. Dimensions for ceiling heights, column spacings, and maintenance aisles are those standardized for universal use in various types of offices some years ago as most economical, taking into account both the initial and maintenance costs of the building and equipment.

The power plant consisting of storage batteries, regular and stand-by charging equipment, regulators, ringing machines and associated control equipment is usually in the basement. It serves switching equipment for one or more central offices on the floors above.

All of the switching components are arranged on the various frames in ways which were calculated to provide the best association for production, service, and maintenance and at the same time facilitate additions for central office growth. Since it is desirable from a cost standpoint to have as much work as possible done

in the factory, the equipment frames carry the largest possible groups of associated apparatus completely assembled, interconnected and tested in the shop. Field installation is in this way reduced to setting up the frames on the office floor, interconnecting them with the interframe cables, and testing the components and the system as a whole before turning it over to the telephone company.

The line link frame is quite similar in appearance to the trunk link frame shown in Figure 6. A number group frame is shown in Figure 7. The frames of the marker are shown in Figure 8 and a typical connector frame in Figure 9. The maintenance equipment in the maintenance center at Media, Pa. is shown in Figure 10.

It is unlikely that two central offices will be identical in numbers of switch frames of the various types or in the equipment provided on them. Some of the things which combine to make each office different are the number of subscribers it serves, the kinds of service they require, the number of times they call, the durations and destinations of their calls; the number of central offices in the same building and in the community; the nature, variety, and number of interconnecting circuits required to provide for the flow of traffic between the office and all other connecting offices. Because the Number 5 system provides so many services and is arranged to connect to so many existing kinds of offices whether in a large or small city, the deviations from office to office are more pronounced than ever before. Custom building is expensive and it was very important in the equipment design to develop the switching frames in a way which would not only provide innumerable necessary combinations of services initially, but also enable facilities to be added and traffic distribution patterns to be rearranged to care for growth, change, and the introduction of new features with the least amount of custom building and the lowest over-all engineering, manufacturing, and installing costs.

While no two offices are expected to be exactly alike, there are features within each that will be the same. Some are required in varying numbers in all offices, others are optional and specified more or less frequently. To meet this situation, a standard package was designed for each basic combination of features and these packages are used as the building blocks for all frame equipments. These standard basic units, which are generally not larger than one or two square feet in area, are reused wherever practicable to concentrate demands on the smallest number of items.

Figure 14. Method of removing rear cover

All Number 5 equipment is arranged in this way in small subassemblies, which are called functional units. Frequently an auxiliary service not required in every office employs one or two relays which cannot be economically packaged apart from a related functional unit. Each such option is coded separately for engineering and administration reasons. It may be furnished always or only as required depending on which arrangement is more economical. All functional units can be bench assembled, wired and tested and, where justified, straight line assembly methods can be employed. Interconnecting wires, precut to length and preskinned, are run along the surface of the mounting plates which support the components and are connected as run. A new wire with plastic insulation was developed for this purpose which reduces wiring congestion, fire hazard, and contact troubles from lint. The elimination of the wire cutting operation at the bench avoids wire clippings in the units. A typical functional unit is shown in Figure 11.

Frame equipment arrangements were similarly standardized to accommodate all needed groupings of functional units completely interconnected and tested in the factory. In order to make each frame as self-sufficient as possible, it is equipped not only with its particular complement of functional units but with fuse panels and all other items which serve it. Every frame arrangement permits the frame and its common equipment and wiring to be manufactured apart from its functional units. Then, at a later stage in the assembly, units and frames can be brought together in a flexible manner as required. Many combinations can thus be assembled from a few standard frames and a relatively few functional units. Each office can be engineered and manufactured with just the features it needs and with as little custom building as practicable. Patterns were developed for frameworks, fuse panels, testing facilities and all other frame equipment and wiring to enable a few parts and assemblies of each type to be brought together in different ways to constitute each standard frame and to permit it to serve any combination of functional units to be mounted on it. Parts, assemblies and patterns were reduced in number by organizing the frame equipments of all types into a few families with strong family resemblances.

Where at all practicable, one frame unit combination was standardized for use on all jobs. The line link, trunk link, and number group frames are in this category. For other frames, except one type which mounts assortments of trunk and miscellaneous units, ways were found to standardize the frame equipment and wiring apart from its units and to provide full flexibility to care for its various complements of units without too great reaction on production. Even in the one exception where the frame equipment and wiring as well as the unit complements vary widely from job to job, a pattern was developed which reduced the custom building and made it relatively easy to administer. As a result, a large proportion of Number 5 frames are fully equipped, wired, and tested in the shop. Space does not permit treatment of each of the patterns developed, but the arrangement for the family of sender and register frames is typical and a description of it will indicate the approach to the problem.

There are nine types of registers and senders in the Number 5 system. In a typical one of these basic types, the originating register for example, Figure 12, the things that vary from office to office include the number of digits which may be received (4 to 9), the number of line link frames in the office, the number of classes of service, the method of translation of digits, and the provision or omission of certain service features. Of the 14 func-

tional units available for originating register services, there are three which are always required with one or another combination of internal variables. These three are for register control, dial pulse counting, and class registration functions. In addition each register will require dial pulse register units in varying quantities depending upon the number of digits to be registered. The units not always required are those for coin service, 2-party test, digit timing, pretranslation and service code functions. Each of the functional units has a standard location in the register and two units are assigned the same location where one or the other, but not both, may be required in any office. Other senders and registers have similar functional units arranged in a similar manner.

By careful organization it was possible to standardize just three frames to care for all nine senders and registers. One of these frames accommodates five originating registers and the line-up of these frames in Figure 5 is typical for all senders and registers. The second frame cares for the four kinds of outgoing senders and the third is for the four kinds of incoming registers. Outgoing senders and incoming registers of the different types may be mixed in any desired combination on their respective frames to minimize frame and floor space requirements. With the frame and unit equipments thus standardized, the senders and registers can be tailored to the needs of each office in the later stages of assembly. For each sender or register frame equipment, one of the three standard frames is selected and on it are mounted the standard units which provide all needed services. Interconnections between the units of any sender or register will usually involve not more than 120 wires which are run loose in a channel provided for them on the rear of the frame. A pattern has been established which enables the shop to interconnect any desired combination of units with just the leads required and without specific job drawings.

A new line of frames and covers was developed for the Number 5 system, also to gain specific advantages in flexibility and in uniformity; flexibility so that the service capabilities of the system could be fully developed with the least restraint from equipment arrangements, and uniformity so that the parts and assemblies would be as few and as alike as practicable in spite of the wide variety of services foreseen. Formed sheet metal sections are used throughout the structure, and front and rear covers of a new design are incorporated, when needed, as part of the frame. In this way any area requiring covering for dust or mechanical protection can be enclosed to the extent desired in a consistent manner. Where maintenance advantages justify the extra cost, transparent plastic covers are substituted for metal.

Figure 13 illustrates the frame construction and the manner in which a front cover can be opened or removed from a frame. Figure 14 shows a rear cover being removed. Horizontal baffles separate the equipment on a frame into compartments of any desired size as shown in Figure 15.

Built into the structural portion of the frame are accommodations for fuse panels, battery filters, appliance outlets, testing and miscellaneous equipment of all varieties required. Each of these items has been reduced to a few standardized designs and all are assigned uniform locations about the base and side uprights of each frame to leave the entire central area free for the unrestricted arrangement of functional units in any combination.

Locations of frames on floors and their interconnections are likewise unified wherever possible. Frame terminations have been reduced to patterns which repeat from office to office. Each frame has power feeders terminated in solderless connectors which the installer can quickly patch to supply grids in the office for battery and commercial power. Cable rack of a new design enables the installer to run cable without sewing or clipping and with little planning; one rack over each wiring aisle serves two lines of frames.

Brief Description of Circuit Operation

Before describing the circuit operation, it may be desirable first to review the principal functions of a dial central office. Such an office is capable of serving about 10,000 subscriber line numbers and is provided with a sufficient number of connecting switches, trunks, and associated circuits to enable calls to be completed promptly under busy hour loads of traffic.

The central office circuits, in response to the lifting of the receiver by the calling subscriber, connect the subscriber line to the switching equipment at which time the dial tone is heard. After dialing, the equipment extends the calling line through several switching stages to the called line as determined by the called office code and line number dialed. When the connection has been established to the called line, the subscriber's bell is rung and, when the subscriber answers, the talking connection is completed. During the conversational period, the connection is held under control of the calling line, and when the telephone receivers are replaced, the central office equipment and

Figure 15 (left). Removal of horizontal baffle

Figure 16 (right). Dialtone connection

Figure 17. Intraoffice call

Figure 19. Terminating call

the telephones are released for use on other calls. The equipment, of course, transmits the busy tone signal to the calling subscriber if the called line is found busy. A call to a discontinued or an unassigned line is automatically routed to an operator who informs the subscriber of the status of such a line.

Operators and associated switchboards are provided in the dial systems to handle certain classes of calls and to render assistance to subscribers when required. Calls to these operators are established in response to the dialing of operator codes in a manner similar to the establishment of calls to other subscribers.

Operators are sometimes provided in dial offices to assist in terminating calls from manual offices. Where this method of operation is employed, the desired number is passed verbally from the operator serving the manual subscriber to the operator associated with the dial terminating equipment (called a *B* operator), and the *B* operator depresses push-button-type keys at the switchboard position which cause dial system equipment to establish connection with the called line. However, with the availability of operator-key-pulsing type equipment, the operators at manual switchboards can transmit signals directly to dial office equipment which then functions to establish connection to the called line in the dial office without need for a *B* operator.

The operation of the Number 5 crossbar system now will be described by tracing the progress of some typical calls through the system with the aid of the simplified block diagrams shown in Figures 16, 17, 18, 19, and 20. The following types of connections will be dealt with in this order:

1. The calling subscriber is connected to an originating register for the purpose of registering the called number which is dialed. This is commonly referred to as a "dial-tone" type of connection.

2. The calling subscriber dials the number of a subscriber who is associated with the same office. This is known as an "intra-office" call.

3. The calling subscriber dials the number of a subscriber who is associated with a distant office. This is known as an "outgoing" call.

4. A subscriber in a distant office dials the number of a subscriber who is associated with this Number 5 crossbar office. This is known as an "incoming" or "terminating" call.

5. A call from a distant office is switched through this Number 5 office to reach a called subscriber in still another distant office. In this case the office is used as a tandem switching point and the call is known as a "tandem" call.

There are, of course, many other kinds of switching connections which this office is capable of handling; however, the above are basic and should give an understanding of the general circuit operation of the system.

Dial-Tone Connection (Figure 16)

A subscriber originates a call by removing the receiver from the switchhook which operates a relay associated with the subscriber's line. The operation of this relay causes the line link frame, through the line link marker connector, to seize one of the idle marker circuits and to inform this marker that a dialing connection is to be established.

The marker determines the identification and location of the calling line. If more than one subscriber line on this line link frame is awaiting service, the marker singles one out for first attention.

At the same time as the marker is determining the identity of the calling line, it also is selecting an idle originating register circuit to serve this call. Several originating registers are associated with each trunk link frame and the marker determines which of the idle trunk link frames has one or more idle originating registers, selects one and connects to this trunk link frame through its trunk link connector. The marker then selects one

Figure 18. Outgoing call

Figure 20. Tandem call

Figure 21. Typical trouble record card

of the idle originating registers associated with the selected trunk link frame. Having determined the location of the calling line, as described before, the marker connects to the line link frame, through the line link connector, and transmits the calling line location information to the selected originating register.

The marker will then choose an idle connecting path to extend the calling subscriber line through line link and trunk link frame switches to the selected originating register. To determine which connecting paths are already in use on other calls and are therefore unavailable for this dial tone connection, the marker tests the line link leads, the junctor leads, and the trunk link leads of the possible paths. The marker selects the preferred connecting path which is available for use and operates the magnets on the crossbar switches to establish this path.

After the connecting path has been established, the marker, the trunk link connector, the line link connector, and the line link marker connector are released and the originating register transmits dial tone to the calling subscriber as an indication that dialing of the called subscriber may be initiated. As the subscriber dials the called subscriber directory number, it is recorded in the originating register for later use in completing either an intraoffice or an outgoing call.

Intraoffice Call (Figure 17)

After the calling subscriber has dialed the complete called subscriber directory number, the originating register, through the register marker connector, seizes an available marker. The originating register transmits to the marker the called directory number and the calling subscriber line location. By examining the office code of the called subscriber number the marker determines that this call is for a subscriber associated with this office. As described in the following paragraphs, the marker then proceeds to establish a connecting path between the called subscriber line and an intraoffice trunk circuit which will be called a "terminating connection", and a connecting path between the calling subscriber and the same intraoffice trunk circuit which will be called an "originating connection".

To establish a "terminating connection" the marker through the trunk link connector, seizes an idle trunk link frame which is associated with at least one idle intraoffice trunk circuit and selects one of these idle intraoffice trunks for service. At the same time as the marker is selecting an idle intraoffice trunk, it also is determining the line location of the called subscriber. To determine the line location of the called subscriber, the marker, through the number group connector, seizes a number group and transmits to it numerics of the called subscriber directory number. The number group translates the called subscriber directory number into line location information and transmits this and appropriate ringing information to the marker. After the marker has received the line location information, the number group connector and number group circuit are released and the marker, through the line link connector, seizes the line link frame associated with the called subscriber line. The called line is tested for busy and, if it is idle, the marker connects the called subscriber line to the selected intraoffice trunk through an available connecting path.

After the marker has thus established the "terminating connection," the line link connector is released and the marker then proceeds to establish the "originating connection." However, if the called line is busy, the calling subscriber is connected through a connecting path to a trunk circuit which transmits a busy tone to the calling subscriber.

To establish an "originating connection" either to the called line or to the busy tone trunk circuit, the marker, through the line link connector, seizes the line link frame associated with the calling subscriber line and connects the calling subscriber line to the selected intraoffice or busy tone trunk circuit, through an available connecting path.

After a talking path has been established from the called subscriber through the intraoffice trunk to the calling subscriber, the marker, the line link connector, the trunk link connector, the register connector, and the originating register are released and the switches are held under control of relays of the intraoffice trunk circuit.

Subscriber Outgoing Call (Figure 18)

After the calling subscriber has dialed the complete called subscriber directory number, the originating register, through the register marker connector, seizes one of the idle marker circuits. The originating register transmits to the marker the called subscriber directory number and the calling subscriber line location. By examining the office code of the called number the marker determines that this call is for a subscriber associated with a distant office.

Assuming that this subscriber outgoing call is to a distant dial office, the marker, through an idle sender connector, seizes an idle outgoing sender circuit and transmits the called directory number to the selected outgoing sender. Having determined that an idle outgoing sender is available, the marker through the trunk link connector, seizes an idle trunk link

frame associated with at least one idle outgoing trunk circuit which connects to the required distant office and selects one of these idle outgoing trunks for service. After the marker has selected both the outgoing sender and the outgoing trunk circuit, the sender link circuit connects the selected outgoing sender to the selected outgoing trunk circuit.

When an idle outgoing trunk has been selected, the marker, through the line link connector, seizes the line link frame associated with the calling subscriber line and connects the calling line to the selected outgoing trunk through an available connecting path. After the connecting path has been established, the marker, the line link connector, the trunk link connector, the sender connector, the register connector, and the originating register are released.

The outgoing sender transmits, by the appropriate pulsing, the called directory number through the sender link and the outgoing trunk to the distant office to provide the information necessary for establishing a connection in the distant office to the called subscriber. The outgoing sender and the sender link are then released and supervision of the call is under control of the outgoing trunk.

Terminating Call (Figure 19)

A call from a distant office is extended to an incoming trunk circuit in the called office. The incoming trunk circuit, through a register link circuit, seizes an idle incoming register circuit. The distant office transmits the called number to the incoming register where it is recorded. Information to identify the trunk link frame which is associated with this incoming trunk is obtained from the register link. The register, through the register marker connector, then seizes an idle marker and transmits to it the called number and the identity of the trunk link frame associated with the incoming trunk.

The call is identified as a terminating call since it is associated with an incoming trunk circuit. The marker, through the trunk link connector, seizes the trunk link frame associated with the incoming trunk. The marker determines the line location of the called subscriber by seizing a number group through a number group connector and transmits to this number group the called directory numerics. The number group translates the called directory number into line location information, and transmits this information to the marker after which the number group and number group connector are released. The marker, through the line link connector, then seizes the line link frame. The called line is tested for a busy condition and, if it is idle, the marker connects the called line to the incoming trunk circuit through an available connecting path.

If the called line is busy, the marker informs the incoming trunk circuit to transmit a busy tone to the calling subscriber.

After a talking path has been established between the called subscriber and the incoming trunk circuit, or after the marker has indicated that the called line is busy, the marker, the trunk link connector, the line link connector, the register marker connector, the incoming register, and the register link are released and supervision of the call is under control of the incoming trunk.

Tandem Call (Figure 20)

A tandem call from a distant office is extended to an incoming tandem trunk circuit in the local office. Each incoming tandem trunk circuit has an appearance on a line link frame similar to a subscriber line as shown in Figure 20. The incoming tandem trunk seizes an idle incoming register circuit. The distant office transmits the called number to the incoming register where it is recorded along with the trunk number obtained from the link to identify the incoming tandem trunk. The incoming register then seizes an idle marker and transmits to it the called number and the identity of the incoming tandem trunk.

By examining the office code of the called number, the marker determines that this is a tandem call and is for a subscriber associated with a distant office. Assuming that this tandem call is to a distant dial office, the marker seizes an idle outgoing sender and transmits to it the called directory number. Having determined that an idle outgoing sender is available, the marker seizes an idle trunk link frame associated with at least one idle outgoing trunk which connects to the desired distant office and selects one of the idle outgoing trunks. After the marker has selected both the outgoing sender and the outgoing trunk, the sender link connects the selected outgoing sender to the selected outgoing trunk.

The marker determines the line location of the incoming tandem trunk from the number group which translates the given trunk number into line location information as described for calls above. The incoming tandem trunk is then connected to the outgoing trunk through an available connecting path after which the marker, the line link connector, the trunk link connector, the sender connector, the register link, the register connector, and the incoming register are released.

The outgoing sender pulses the called number through the sender link and the outgoing trunk to the distant office to provide the information necessary for establishing a connection to the called subscriber in the distant office. The outgoing sender and the sender link are then released and supervision of the call is under control of the incoming tandem trunk circuit. The incoming tandem trunk circuit also can be used for calls which terminate in this office.

Maintenance Provisions

In the development of the Number 5 system, it was a major design objective to produce a system which would be more nearly trouble-free than any system produced heretofore. In addition, if troubles could be made sufficiently infrequent, an office could be unattended for long periods of time with a resulting reduction in maintenance effort, testing facilities and maintenance costs.

Steps which have been taken toward these maintenance objectives include the following:

1. In designing circuits there was an endeavor to employ relays and switches in arrangements which would enable these devices to perform their required functions with maximum ease and allow maximum tolerance of maladjustment. This provides margin to allow for changes in operating characteristics which are inevitable as a result of apparatus wear, aging, and other factors.

2. Contact locking and contact erosion has been minimized by extensive use of contact protection networks.

3. Many self-checking and trouble detecting features are included in the common control circuits, particularly the marker. When a trouble is detected, a card record, Figure 21, is made by the trouble recorder. Meanwhile, wherever possible, a second trial is made to establish the connection for the subscriber. Because of the extensive use of the marker for switching operations in this system, these features are more effective than in any earlier system.

4. A new device known as an "automatic monitor" has been provided and is arranged to check, automatically on a sampling basis, the pulsing features of the registers and senders while handling regular service. When troubles are found, the trouble recorder is engaged and a record made.

5. As mentioned before, a new trouble recorder, Figure 22, was developed for the Number 5 system. This is a type of per-

forator which is engaged by a common control circuit when trouble is encountered and makes a card record of essential information which can be used by the maintenance force as an aid in locating the trouble. It will automatically record a succession of trouble indications and is sufficiently fast in its operation to record a large volume of indications within a short period of time and to minimize delays to the circuits which encounter troubles. The Number 5 system also makes extensive use of the trouble recorder to indicate test results.

6. Portable test boxes and frame mounted test circuits are made available for testing and maintaining circuits such as senders, registers, trunks and markers, and other circuit elements.

7. A simplified form of central office audible and visual alarms has been provided to direct attention to the presence of trouble conditions. The alarms are arranged to be transmitted to the maintenance force at another location when the office is unattended and under these conditions, an indication as to the nature or degree of trouble is given.

Maintenance activity in crossbar offices is controlled from a "maintenance center." This is the area in which all of the principal frames used in testing and trouble recording operations are located. In Number 5 crossbar this activity is controlled from the "master test frame." This is actually a group of frames and includes the trouble recorder, the automatic monitor, register and sender test, trunk test, and the associated circuits, including the master test frame connector which provides access to the various circuits for testing. Located here also are facilities which quickly permit taking any of the major circuits out of service to minimize trouble reactions. It is possible to obtain access to and test any of the individual major circuits in the office from the master test frame.

Summary of Number 5 Crossbar's More Important Features

1. The Number 5 system permits direct interconnection with all existing types of crossbar, panel, step-by-step, and manual offices. It can be used for a variety of sizes of offices with heavy or light traffic and can operate with few or many interconnecting offices of the various kinds. It also can operate with various types and combinations of numbering plans involving anywhere from 4 to 11 digits.

2. The Number 5 system has the ability to operate as a toll or tandem switching center for a moderate amount of toll

Figure 22. Trouble recorder

or of tandem traffic. In this respect, it includes arrangements which conform to plans for future nation-wide toll dialing.

3. The system is designed for long service life with a minimum of maintenance attention and prolonged periods of unattended operation. In the event of certain trouble conditions within the system, the second trial feature serves to maintain unimpaired service to the subscriber. Ample margins of circuit operation are included in the design to take care of changes in apparatus operating characteristics over the years. To a much greater extent than ever before, protective means have been applied to prevent destructive erosion of apparatus contacts.

4. The Number 5 system exploits the common control principle to a greater extent than any previous system. The common controls are concentrated in a small group of markers. Depending on its size, from 3 to 12 of these will serve any Number 5 office.

5. The equipment arrangements utilize the flexibility inherent in the switching plan and in the circuit arrangements and at the same time provide standardization which tends toward efficient manufacture, job engineering, installation, and maintenance.

6. As many as 30 classes of service for lines (individual or party with flat rate, message rate, coin or extended scope service) can be served through just one design of line link frame and one design of trunk link frame. Lines and trunks in any combinations are cared for by these two basic switch frames.

7. Every intraoffice and incoming trunk circuit in the Number 5 system can complete universally to any line and any party on it regardless of variations in ringing signals. This is so since each of these trunk circuits is represented by one vertical on a ringing switch which, when properly primed by the marker, sends out the correct ringing code on either tip or ring side of the called line.

8. Trunk circuits of each group are distributed as uniformly as possible over all trunk link frames, yet each type comprises a single efficient group and a marker can find any idle trunk of a group on any trunk link frame.

9. The addition of new features is facilitated as shown by the following:

(*a*). In the event that a new device to replace the dial as a calling instrument is developed in the future, the Number 5 system is adapted to accommodate such an arrangement and will do it economically. A new group of originating registers to respond to the signals from such a device would be provided in quantity as needed to serve the originating traffic offered by the subscribers provided with such devices. Both the present dial-pulse type and the new type of originating registers could be used in the same office and both would be associated in the same way with the trunk link frames, but an appropriate line link frame signal would cause the marker to associate the line with the proper type of register. Lines of the new type could be added in large or small quantities without disturbing the normal operation of a working office.

(*b*). In the Number 5 system, the method of associating a sender directly with the outgoing trunk circuit on calls to dial offices, (and manual *PCI*), and the availability of the various kinds of senders mentioned previously, provides a maximum degree of flexibility for inter-office pulsing signals. The senders of each type are relatively simple. They are furnished only when their specific services are required and then in only the quantities needed to handle the traffic in the particular office. If new inter-office pulsing systems are developed in the future, new groups of senders can likewise be provided economically for use with only those trunk circuits which are associated with the new facilities.

No Discussion

Fundamentals of the Automatic Telephone Message Accounting System

JOHN MESZAR
MEMBER AIEE

RECENTLY, automatic message accounting (AMA) systems have been placed in commercial service by the Bell System in the Philadelphia and Detroit areas. These systems record in the central offices all the data required to charge for subscriber dialed telephone messages, both local and toll, and process this record in accounting centers through computing, sorting, summarizing, and printing machinery. Both the recording and processing arrangements have many unique technical aspects.

The AMA system is a major contribution to telephony. Its use will permit wide expansion of direct subscriber dialing to nearby and more remote points, with resultant increased economy, speed, and convenience to telephone service customers.

This paper discusses the economic background of the AMA system, explains its fundamental coding technique, describes its unique apparatus elements, and presents the basic features of both the recording and processing machinery.

Economic Background of AMA

It will be readily admitted by everyone that collection of earned revenue is essential for successful business. Before revenue can be collected, however, most business firms have to prepare and present bills to their customers.

Telephone companies have unique problems in preparing bills. They sell tailor-made service items to millions of customers. Each service item consists of putting temporarily at the customer's disposal an impressive physical plant, and a skilled human organization, to enable him to communicate at will with his family, friends, business associates, around the corner or thousands of miles away. A very large proportion of these service items is of truly low price. Although the Bell System, for example, is a multibillion dollar concern, its revenue is derived primarily from service items, a great many of which bring into the kitty only 5 cents or even less. There are, of course, items that bring in 10 cents, 15 cents, 20 cents, or higher, but even these can be honestly classified as low priced service items. What runs up the system's total annual revenue into hundreds of millions of dollars is the enormous volume of these low priced service items. In 1948, the Bell System handled, on the average, every minute of the year approximately 100,000 telephone conversations for customers who number upwards of 25,000,000.

It does not require much imagination to appreciate that the accounting and billing problems of such a business must indeed be great. These problems are, of course, eased by the fact that much of the Bell System's local telephone service is rendered on a "flat rate" basis, meaning that the payment by the customer of a fixed monthly sum entitles him to make an unlimited number of telephone calls within a specified local area. In great metropolitan centers, however, such as in the New York area, and under other conditions as well, local telephone service is metered. Metered service is rendered on a "message rate" basis, meaning that each completed call, even though within the local area, is individually charged for in terms of "message units." A local call may be worth one or more message units, and the telephone service rate structure uses four parameters for determining its value: that is, (a) variable intervals are allowed as initial conversation periods; (b) variable message unit values are assigned to these initial periods; (c) variable intervals are allowed as overtime periods; and (d) variable message unit values are assigned to these overtime periods. A particular combination of these four variable parameters is designated by an arbitrary number and referred to as the "billing index" of the call. Table I illustrates a message unit rate plan.

Message-unit type calls are referred to as "bulk-billed" calls because individually they are not listed on the customer's bill. Only the aggregate charges for all such calls in a billing month are shown. These charges are determined by converting the total message units of a billing month into dollars and cents prior to billing. The conversion factor may be, for instance, four cents per message unit or some other higher or lower value. (Metered service is, in general, offered on the basis of the customer paying a fixed minimum monthly sum, for which he is allowed a stated number of message units during the month. Message units used above this allowance are then charged for at the prevailing rate.)

Irrespective of whether local service is on the flat rate or message rate basis, calls to points outside the specified area are "toll" calls. The significant thing about toll calls from the accounting and

Paper 50-42, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 1, 1949; made available for printing December 1, 1949.

JOHN MESZAR is with the Bell Telephone Laboratories, Inc., New York, N. Y.

billing standpoint is that they are listed individually and chronologically on each customer's "Toll Service Statement", which accompanies the bill. Furthermore, on this service statement, pertinent details of each toll message are shown, such as the date of the message, its destination, and its price. The determination of the price of the message has to take into account such factors as distance between calling and called areas, duration of conversation, the date and time of the call, and so forth.

One would think that only relatively high priced calls have to be identified in detail on customer's service statements. This is not so. Existing telephone rate structures, which are subject to state and federal government regulation, are such that a sizeable volume of even 5 cent or 10 cent calls are detail-billed toll calls. Table II gives some interesting Bell System figures.

As this table shows, there were in 1948 about 1.2 billion annual toll messages of 35 cents or less. Of the 1.2 billion about 50 per cent were 5 and 10 cent calls. The 450 million messages over 35 cents are the ones generally classed as long distance toll.

Two closely related factors should be emphasized at this point. The first is that most toll messages, even those priced at only 5 cents, are handled by operators at switchboards, in order to record on individual tickets the details required by the billing technique. Second, the billing technique itself is, in turn, greatly complicated by the necessity of carrying the originally recorded details of each toll call through the complete process.

In view of the foregoing, there is obviously an intense need to handle ever more efficiently the great volume of low revenue telephone service items. The urge is two fold: to improve the economy of establishing telephone connections; and to improve the economy of billing for the service. In the first area, one answer is the ever wider extension of automatic connecting methods, which permit both customers and operators to dial over greater and greater distances. In the second area, a most promising answer is the recently developed AMA system.

Existing Telephone Message Accounting Methods

While telephone message accounting today is mostly manual work, it makes full use of such modern office equipment as bill printing and addressing machines, inserting and mailing machines, and so forth. Furthermore, the bulk-billed messages are mostly automatically metered by individual subscriber message-registers. These registers score one or more counts for each chargeable message and indicate the total of such registrations. Manual work is, of course, involved in reading these registers, in subtracting the preceding month's registration from the current month's registration, and in arranging the net usage figures in telephone number order, to match the order in which subscribers' records are kept.

Table II. Bell System Toll Messages—Estimated for 1948

Charging Rate	Number of Messages, in Millions
5¢	140
10¢	450
15¢	260
20¢	140
25¢	90
30¢	70
35¢	50
Total 5¢–35¢	1,200
Over 35¢	450
Total	1,650

Another partial exception to manual accounting in the Bell System is used in the Los Angeles and San Francisco areas. Here, in certain step-by-step type dial telephone offices, multimessage-unit traffic is recorded automatically on slips of paper by a system called "automatic ticketing."[1]

It is not the bulk-billed message-unit type calls, however, but the detail-billed toll calls that offer the best opportunities for more economical operating and accounting techniques than have been used in the past. As stated previously, most of these calls today are established by operators in order to record on individual tickets the necessary billing details. The operator tickets are forwarded daily in packages from the operating telephone offices to an accounting center, where the accounting work is done for a group of offices. The staff of a typical accounting center may handle over a million operator tickets a month for, say, a quarter of a million customers. These tickets have to be timed, rated in dollars and cents, sorted into calling telephone number order, transcribed (by typing) onto customers' toll service statements, totalled, taxed, and finally posted on the customers monthly bills. This is a bare outline of what an accounting center has to do with over a million pieces of paper every month. Extra steps are superimposed for intercompany revenue settlements, for collecting essential statistics, for checking accuracy, and so forth.

In spite of the fact that this telephone message accounting is essentially manual work, through many years of intense effort it has been brought to very high efficiency. The ultimate objective of automatic techniques, such as the AMA system, is, of course, to make it even more efficient and economical by mechanizing the whole process, beginning with the initial recording of the required data, and ending with the printed monthly bill mailed to the customer. This is a major objective, and it was decided in the early stages of the AMA development not to try to accomplish it all at once. A more modest initial goal had been set instead, which called for the full development of the automatic recording technique in certain types of dial central offices, but assumed only partial mechanization of the accounting center processing.

Fundamental AMA Coding Technique

For each telephone message, the essential billing data are: (a) the identity of the calling customer who will foot the bill; (b) the identity of the called telephone; (c) the exact time that conversation starts, generally referred to as the "answer time"; (d) the exact time that conversation ends, generally called the "disconnect time." For bulk-billed calls it is not necessary to record the called telephone number. Instead, the arbitrary one digit billing index may be recorded to represent the charging treatment applicable to the call.

In addition to the data individual to each telephone message, there are certain items of information which are common to large groups of calls, and hence need be recorded but once. In this category are such data as the month and date of the calls, the identity of the recording central office, and so forth.

All of this information can be conveniently expressed in numbers. The calling customer is identified in terms of his telephone number. The called telephone is dialed of course as a number. The date of the call is one of 12 months and one of 31 days. The time at the beginning and end of the conversation is stated in hours, minutes, and tenths of minutes. Billing indices and all other incidental information also can be expressed in terms of numbers.

Thus, in the central office, the AMA system needs to record only appropriate numbers. This record of the original billing data has to be semipermanent for use subsequently in the accounting center. In fact, most telephone companies pre-

Figure 1. Section of central office AMA tape showing pattern of perforated holes

serve the central office record for several months. The AMA recording is done, therefore, in the form of patterns of holes on a 3-inch wide paper tape. The tape is supplied in 3,000-foot sections, and by splicing sections, the equivalent of a continuous supply is available. Figure 1 shows a piece of central office AMA tape. Across this AMA tape there are 28 hole-positions, divided into one group of three (referred to as the *A* digit), and five groups of five (referred to as the *B*, *C*, *D*, *E*, *F* digits). The *B*, *C*, *D*, *E*, *F* digits are each used to record a decimal (0 to 9) digit. This is done by perforating in each digit two out of five possible holes. There are exactly ten combinations of two out of five holes, or just enough to represent the ten values of a decimal digit. Rather than using arbitrary pairs of holes to represent the ten values, the five hole positions are designated

0, 1, 2, 4, 7,

and a digit is represented by punching the two holes whose designations add up to its value. Thus "1" is represented by punching holes designated 0 and 1; "2" is represented by punching holes designated 0 and 2; and so forth. There is a single exception to this additive arrangement. The digit "0" is represented by punching holes designated 4 and 7. Since this is the only exception to the additive rule, it can be easily remembered.

This so-called "2-out-of-5 additive code" is of fundamental importance in the AMA system. It is used not only in recording information on the central office paper tape, but is woven into the relay circuitry throughout the system. It requires only five elements, holes or relays, to represent any one of ten values and, even more important, its rigid pattern of two and only two elements out of five permits a constant, precise automatic check for correctness.

Since the *B*, *C*, *D*, *E*, *F* digits of the AMA tape can represent decimal digits, any 5-digit number can be recorded in one row of holes across the tape. The *A* digit has room for only three holes. To preserve the AMA system's rigid checking technique for valid combination of elements, these three hole positions are used to represent only one of four values by punching any one, or all three, of the holes, but never two holes. Thus a complete row of the 28-hole positions, *A* to *F* digits inclusive, is good for any one of 400,000 valid combinations of holes, representing any number from 000000 to 399,999. Figure 2 is a representation of a typical line of tape record. The black circles stand for perforated holes, the white ones are unperforated hole positions. The staggering into upper and lower rows is done only for physical spacing reasons in perforating mechanism.

AMA 6-Digit Number Language

Elaborations of the fundamental numerical representation just described are used to express all information the AMA system has to deal with. The information is always stated in terms of six digit numbers. Of these six digits, one or more are used as a code to specify the nature of the associated information. Thus, "282" in the *A*, *B*, *C* digits of the central office tape, for example, is the code which specifies that: "The associated *E* and *F* digits represent the date on which the recorded telephone calls were made." The verbal statement: "These telephone calls were made on the fifteenth day of the month" would, therefore, be stated in AMA language as

282015

The 0 in the *D* digit is simply a filler-in to satisfy the six digit requirement.

In the same manner, "283" in the *A*, *B*, *C* digits is the code which specifies that: "The associated *E* and *F* digits represent the month in which the telephone calls were made". The verbal statement: "These telephone calls were made during the month of December" would, therefore, be stated in AMA language as

283012

Not all codes specifying the nature of information are of three digits. For example, the number "1" alone in the *A* digit of the central office tape is used to specify that: "The associated *B*, *C*, *D* digits represent the time when a particular conversation started, and the *E*, *F* digits contain a number which identifies this conversation." (The significance of this identity number will be brought out later.) The AMA statement

148632

means that conversation number 32 started 48.6 minutes after the last recorded hour.

As one more example, the 2-digit code "23" in the *A*, *B* digits of the central office tape defines the significance of information contained in the associated *C* to *F* digits, as well as in the immediately succeeding three lines of digits. These four lines represent the full initial information available on a detail-billed call at the completion of subscriber dialing. A typical pattern specified by the code 23 is as follows:

239011
045665
081677
032356

In this pattern the 0 in the *D* digit of the first line is again a filler-in. The O's in the *A* digits denote supplementary lines of information.

The verbal equivalent of this AMA statement is: "A call has been initiated which will have to be detail-billed (23); the call is to be charged for in accordance with toll rate structure (9); the call is labelled number 11; the calling central office is designated number 4; the telephone number of the calling subscriber is 5665; the geographic area of the called place is designated number 8; the called

Figure 2. Representation of a line of AMA tape record

Figure 3. Representation of starting pattern of central office AMA tape

telephone number may contain a party letter (this information is conveyed by value 1 in the *C* digit of the third line); the called telephone office is 677 (this might be, for example, ORange 7); the called number is 32356 (since the last digit of this number corresponds to a party letter, the system will deliver it at its output as 3235M).

Enough examples now have been given to illustrate the AMA number language. In this language each statement is called an "entry." An entry consists of one or more 6-digit-numbers whose digits have a precise significance.

Central Office AMA Recording—General

The information required for billing for dialed telephone message service can only be collected within the central offices. It is the switching mechanism in the central office into which the calling subscriber dials his request for a telephone connection. It is the switching mechanism of the central office that determines his identity, establishes the requested connection, and times the conversation.

As stated before, the basic information per call required for billing purposes is: the calling telephone number, the called telephone number, the time conversation starts, and the time conversation ends. Each of these bits of information can be recorded automatically in a fraction of a second. Therefore, the tying up of a recorder with an individual call of minutes duration is unnecessary. In the AMA system one recorder is used for as many as a hundred calls that may be simultaneously in progress. Depending on its size and traffic characteristics, a central office of the crossbar type, to which AMA is applicable, may carry up to 2,000 simultaneous conversations, thus requiring a maximum of 20 AMA recorders. Each recorder uses a hundred numbers (00 to 99) to label its simultaneous calls. Physically, these 2-digit labels are assigned to the transmission channels (trunks), one of which is allotted to a calling subscriber by the dial switching mechanism for the duration of his call. An AMA recorder works with a particular group of 100 trunks, and is automatically connected to one of them only when billing information need be recorded for a call established over that particular trunk. Normally, per call, there are three such instances of association. First, the "initial entry" (calling and called telephone numbers) is recorded when the dialing has been completed by the calling subscriber. Second, the "answer time entry" is recorded when the conversation starts. Third, the "disconnect time entry" is recorded when the conversation ends. These entries are recorded by the common recorder in a chronological order as they occur on the various trunks. The central office tape from a recorder is in effect a log book of the billing events that occurred on a group of 100 trunks. Obviously, this recording technique results in the entries of the various calls getting interleaved. However, each entry of a particular call is identified by the same label, which is the two digit number of the trunk assigned to transmit the conversation. This is an important point to which reference will be made later in describing how the AMA accounting center processes the central office tape.

In addition to the individual call entries, the over-all accounting and billing job requires the recording of certain incidental information. For instance, information common to all calls, such as the month, day, recorder number, and so forth, is recorded right at the beginning as well as at the end of each tape. Also, the hour of the day is recorded every hour on the hour. Furthermore, since the central office tape has to be sent every day or every few days to the accounting center, it must be periodically cut. To mark the most convenient cutting spot, a distinct pattern of holes is automatically perforated at the right spot of the tape. The code for this pattern is 081010, and enough consecutive lines of this code are recorded to permit convenient cutting and subsequent handling. The 081010 pattern of holes is called the "splice pattern," because it also permits splicing tapes end-to-end without mutilating any of the useful information on the tapes.

A starting pattern of a central office AMA record is therefore as indicated on Figure 3. Figure 4 in turn represents a section of the central office AMA tape.

AMA Recording Apparatus

The unit that actually makes the pattern of holes in the AMA tape is called the perforator. Figures 5 and 6 present two different views of this perforator, and its

Figure 4. Representation of a section of central office AMA tape

Figure 5 (left). Top view of AMA perforator

Figure 6 (right). Bottom view of AMA perforator

basic features are shown on Figure 7.

The perforator has 28 electromagnets, any valid combination of which can be energized by control circuits. When energized, each magnet pushes a mechanically coupled steel pin through the paper tape. The points of the 28 steel pins are physically concentrated into a row across the tape, with alternate pins slightly offset into an upper and lower row. The tape lies on the circumference of a cylindrical drum which has a countersunk hole opposite each steel pin. All the required holes for a 6-digit number are perforated at once. In most cases this means perforating 11 out of the possible 28 holes, 2 out of 5 for the *B*, *C*, *D*, *E*, and *F* digits and 1 out of 3 in the *A* digit. Occasionally the *A* digit requires three holes, and in this case a total of 13 out of the possible 28 holes is perforated all at once. As soon as the holes have been perforated, the electromagnets are de-energized, resulting in the withdrawal of the associated steel pins from the tape. Then the drum turns 1/10 of an inch, moving the tape with it. The tape is now ready for the next row of perforations. The perforated tape and the drum constitute a self-gearing arrangement without the necessity for any sprocket holes.

Blank tape is pulled by the perforator out of a bin which is replenished in such a manner as to give the equivalent of an endless supply. The perforated tape is reeled up automatically as it develops slack. Figure 8 shows a complete perforator cabinet with two perforators.

Central Office AMA Circuits

The relay circuits controlling the central office AMA perforators are not simple. Some of this circuitry is intimately integrated into the dial switching mechanism of the central office, but there are major units that are used exclusively for AMA. None of the circuits will be discussed here in detail. It is appropriate to say, however, that, like their companion switching circuits which automatically establish the telephone connections, these AMA circuits represent some of the most intricate creative accomplishments of the human mind. The jobs these circuits perform, and the precision and speed with which they work, are truly remarkable. To gain a general idea of what is involved, a functional block diagram of the AMA circuits in the Number 5 crossbar dial switching system[3] is shown in Figure 9, and Figure 10 shows one of the functional units. The following brief description of the basic AMA recording features is based on this diagram.

When a subscriber initiates a call, one of the "markers" which are the brainiest, costliest, and hardest working circuit units of the number 5 switching system, connects his line automatically to an "originating register" circuit unit, from which dial tone is received. This simple statement covers the job of spotting and identifying the calling subscriber amongst perhaps 20,000, of determining the class of service he is paying for, of searching and locating an available register from amongst dozens, and of choosing an appropriate one of several hundred thousand combinations of linkages within the central office to connect the particular line to the particular register. It also should be mentioned incidentally that the marker accomplishes all this in about a half a second, and that this interval includes passing the calling subscriber's identity and class of service into the register. Figure 9 shows the subscriber-to-register dialing connection in dotted, since it is part of the regular switching operation and precedes the AMA functions.

The subscriber now dials the desired telephone number into the register, which stores this information. During this dialing time the marker is attending to the needs of other subscribers.

Once the register has received the complete wanted number from the subscriber, it connects itself to an available marker, and requests this marker to set up the connection between the calling and called numbers. The marker first determines, from the relationship of the calling subscriber's class of service and the called number, that the call is a chargeable call, that a certain rate treatment is applicable to it, and that the called party has to be reached, say, via another central office. The marker then proceeds to select an available AMA type "outgoing trunk" to the desired central office and starts the job of establishing the connection between the calling subscriber and this chosen outgoing trunk. The job of establishing this connection is of the same nature as was that of establishing the connection between the calling subscriber and the register. This job also is an integral part of switching. The sole contribution to AMA is the choice of the proper type of outgoing trunk.

Recording the Initial Entry

Coincident with the selection of the outgoing trunk, the marker also selects an appropriate "outgoing sender." This is the circuit unit in the switching system whose primary function is to send the called number to the completing central

Figure 7. Basic features of AMA perforator

Figure 8. Perforator cabinet showing tape supply bins, perforators, and take-up reels

office at a time and in a form acceptable to that office. AMA superimposes another major function on this unit, which is to store temporarily certain billing data that the marker has determined, and which will eventually be recorded on the AMA tape. This is done, of course, to permit the marker to release from the call at the earliest possible moment to serve other calls. Typical AMA data stored in the sender by the marker are: (a) the identity of the calling subscriber; (b) the called number; (c) the message billing index for the call; and (d) the identity of the recorder which serves the selected trunk.

When the marker is almost finished with its work of establishing the connection from the calling subscriber to the outgoing trunk, it notifies the sender to connect itself to the "transverter." The transverter is exclusively an AMA circuit unit of some complexity. Its over-all function is to convert the initial information for the call into the 6-digit numerical AMA language, and to control the recording of this entry.

As soon as the sender connects to the transverter, it sends enough information into the transverter regarding the identity of the calling subscriber to enable the transverter to connect itself, in turn, to an appropriate "translator." The translator is also exclusively an AMA circuit unit of intriguing performance. Its over-all function is to translate the calling subscriber's identity into his telephone number. This function makes sense only when it is realized that the subscriber's identity is determined originally by the marker in terms of the central office equipment number to which his line is wired. To care for changes in traffic requirements, connection of new subscribers, and so forth, the relationship between subscriber line equipments and telephone numbers is made flexible, and the translator is, in effect, an ingenious electromagnetic card file system, which is "consulted" by the transverter to obtain up-to-the-minute information on this relationship. One unit of the translator corresponds to one of 20 drawers of the card file, each having a 1,000-card capacity. Once the appropriate translator unit is seized by the transverter, the complete central office line equipment number of the calling subscriber is transmitted to it partly by the transverter and partly by the outgoing sender via the transverter. In an instant, the translator returns the correct telephone number of the calling subscriber. The transverter memorizes this telephone number and dismisses the translator unit to serve other calls.

The transverter and sender, between them, now have most of the information necessary to record the initial entry of the call. The only missing item is the number of the selected outgoing trunk, which is required as a call-identifying label. On the basis of the recorder number given earlier to the sender by the marker, the transverter now connects itself to the "recorder." The recorder also is exclusively an AMA circuit unit containing the perforator and the paper tape supply. Through the transverter, the complete AMA statement for the initial entry is then furnished to the recorder and is perforated on the tape one line at a time. When it is time to perforate the line which requires the call-identity label, the transverter requests this information from the trunk via the "sender link" path. The trunk, with the aid of the "trunk identifier," another exclusively AMA circuit unit, furnishes the 2-digit call label in AMA form direct to the recorder. When the perforating of the initial entry is finished, the transverter and recorder release. The sender also restores to normal, provided that it had already finished its switching job of transmitting information to the completing central office.

The recording of the complete initial entry takes but a fraction of a second.

Recording the Answer Time Entry

If a call encounters a "line busy" or "don't answer" condition, obviously no time-entries are recorded for it. When a call is answered, the supervisory function of the outgoing trunk comes into play to signal the appropriate recorder through the trunk identifier. As a result, the recorder perforates the call identity label, and the time of day at that moment in terms of minutes and tenths of minutes. The recorder keeps track of time within itself under control of a common "master timer." The master timer is one more exclusively AMA unit. It is a circuit comprising a complete electrical calendar and clock.

Figure 9. Central office AMA functional block diagram

Figure 10. Front view of AMA master timer frame

Recording the Disconnect Time Entry

When the calling subscriber terminates the connection, the trunk via the trunk identifier again requests the recorder to perforate the time of day and the call identity label in the same manner as for the answer time.

Recording of Entries Common to Groups of Calls

It was already mentioned that there are certain entries recorded infrequently on the AMA tape, because such entries are common to groups of calls. Common entries are perforated by the recorder under direct control of the master timer. Thus, every hour on the hour the master timer connects itself to the recorder to perforate the hour information. The code for the hour is

2810XX

where XX is from 00 to 23. Midnight is the 00 hour.

Also, at 3 a.m., the master timer controls the perforation of the cutting or "end-of-tape" pattern which includes the month, day, recorder number, central office identity number, and so forth, followed by splice pattern. (3 a.m. was chosen because at that time the least number of telephone calls are in progress in the central office.) After the splice pattern is perforated, another set of the month, day, and so forth, entries are recorded to serve as the beginning pattern for the next day's business. The tape may be cut at the 3 a.m. splice pattern any time after 3 a.m. and transported to the accounting center.

Principles of the Translator

Earlier the statement was made that none of the circuit units of the central office will be described in detail. An exception will be made to this statement by introducing at this point a brief presentation of the principles of one unit, the translator. The translator is singled out both because its use illustrates an important practical problem AMA has to deal with, and also because of the ingenuity of its technical features.

The practical problem referred to comes about this way. The two wires of a subscriber's line terminate within the central office in an appropriate type of individual "line equipment". These line equipments are the subscribers' entrance points into the switching system. Line equipments are, of course, physical entities. For example, in a crossbar-type central office a line equipment consists of a line-relay and a crossbar switch vertical unit. These line equipments are designated by numbers which specify their location in the central office. It is in terms of this "line equipment number" that the marker in the Number 5 crossbar system originally identifies the calling subscriber. But, a telephone subscriber's ultimate identity is in terms of his telephone number, and these two numbers, that is, the line equipment and telephone numbers, are not at all identical. The problem of translation from one into the other would, however, not be troublesome if it were not for the fact that, for many reasons, the association between a subscriber and a particular line equipment does not stay put. Subscribers may change their class of service, requiring a new type of line equipment. Growth in the size of central office results in periodic rearrangement. Also, call congestion may develop in certain portions of the central office switching system, requiring subscriber line redistribution. Furthermore, a party-line equipment is used by several subscribers, with different telephone numbers. For these and other reasons, the problem of determining the exact relationship at any one time between telephone numbers and line equipment numbers is a troublesome

Figure 12. Basic features of AMA tape reader

Figure 11 (above). Simplified schematic of AMA translator

Figure 13 (right). AMA tape reader

one. Figure 11 is a much simplified illustration of the AMA translator which is an ingenious solution of this problem.

Physically, the unit consists first of a row of terminals at its top, each of which represents a subscriber line equipment number. Below this row of terminals are five shelves, on which rest doughnut-shaped transformers with secondary windings only. The ten transformers on the first shelf are used to obtain the "thousands" digit of telephone numbers; the ten transformers on the second shelf are used to obtain the "hundreds" digit; the ten transformers on the third shelf are used to obtain the "tens" digit; and the ten transformers on the fourth shelf are used to obtain the "units" digit of telephone numbers. On each of these shelves the ten transformers are designated 0 to 9. There is a fifth shelf for use where the switching system is of the multioffice type. The transformers on this shelf are used to determine the office of a calling subscriber.

The terminals at the top are so designed that the bare end of a piece of insulation covered wire can be connected quickly to any one of them by solderless connection.

This piece of wire then represents a subscriber line equipment number. If the telephone number of the subscriber using the particular line equipment is, say, 3682, the wire is snaked through the doughnut hole in transformer number 3 on the "thousands" shelf, then through transformer number 6 on the "hundreds" shelf, transformer number 8 on the "tens" shelf, and transformer number 2 on the "units" shelf. In a multi-office switching system the wire is also snaked through one of the transformers on the last shelf, to obtain the office of the calling subscriber. The leading end of the wire is then connected, also by solderless connection, to an individual terminal at the bottom. The location of this bottom terminal is symmetrical with that of the top terminal.

The wire thus snaked through the holes of the particular transformers becomes in effect a single turn primary winding for these transformers. The secondary windings on the doughnut-shaped cores are coupled to this single turn primary through air, but they have many turns and are connected into voltage sensitive cold-cathode gas tube circuits, as is shown on Figure 11.

With this physical picture in mind, the operation of the translator is simple to understand. When it is called upon by the transverter to furnish the telephone number corresponding to a particular calling line equipment number, the transverter sends a heavy momentary surge of current through the wire representing the line equipment number. Due to the large turns-ratio, this primary current induces enough secondary voltage in the transformers involved to fire the associated gas tubes, which in turn operate their companion relays. The output, representing the thousands, hundreds, tens and units digit of the subscriber's telephone number, as well as his central office, is taken from the contacts of these relays.

In offices having party lines, separate translators are used for each corresponding group of parties. The originating register determines which party is calling, and the transverter is thus enabled to choose the appropriate translator.

It is obvious from the foregoing description that when a particular subscriber line equipment is reassigned to a new telephone number, only one wire need be pulled out and re-snaked through the appropriate transformers. This is a simple and quick operation, and thus the recurrent rearrangements in the central office between subscriber line equipments and telephone number assignments constitute but a reasonable burden on the AMA system.

Epilogue: Central Office AMA Facilities

The preceding description is a bare outline of the functions of the AMA circuits in a crossbar-type central office. While details were not discussed, a little imagination will conjure up hundreds of relays busily clicking away in various intricate hook-ups to record the billing data for thousands of telephone calls per hour in a central office. Such a vision is aided by the relay figures in the various circuit blocks of Figure 9, and the number of leads between the blocks over which these circuits "talk" to each other. Further, what has been presented is only the simple, straightforward AMA job in the central office. The commercial design has to guard the accuracy and integrity of the recorded data in spite of possible irregularities and malfunctionings. Thus, provisions have to be made for substitution of an emergency recorder for any of the regular recorders in case of trouble; for detecting falsely grounded or crossed leads, or open relay contacts, before they can cause wrong charging; for checking that the basic 2-out-of-5 AMA pattern is never violated; for insuring that the paper tape is moved after each perforation; for guaranteeing that the relay calendar and clock is precise; and so on.

The AMA Accounting Center—General

The accounting center is the place where the message accounting work is done for a number of telephone offices. An average accounting center may handle the accounting work for about 250,000 telephone subscribers. The ultimate "end-product" of the message accounting process is, of course, the subscriber bill and toll service statement. These bills and service statements are sent out once a month, but a billing period does not necessarily coincide with a calendar month. To spread the accounting workload evenly over the full calendar month, the staffs of most accounting centers prepare and mail bills to subscribers in different groups of central offices every five days. Thus bills are dated as of the first, sixth, eleventh, sixteenth, and so forth, of the month. Such accounting centers are said to work on the 6-billing period basis. There are also accounting centers that work on a 10-billing period basis. In such offices a different group of bills is prepared every three days.

While a group of bills is prepared every three or five days, collection of the central office AMA tape is generally done daily. This is not a necessity, but a convenience. The accounting center staff can thus finish certain steps of the processing daily, before accumulating either three or five days work into a "round" for subsequent processing.

It was stated at the outset that the scope of the initial AMA development included the complete central office recording technique, but visualized only a partial mechanization of the accounting center processing technique. This decision required setting a suitable cut-off point, where the output of the AMA system would conveniently merge into present manual message accounting practices. It is well to keep this point in mind, in order to appreciate the present end-products of the AMA system.

The AMA accounting center processing technique puts the central office data through a series of machines. These machines are designated in the order of their sequential use as: the assembler, the computer, the sorter, the summarizer, and the printer. The first of these machines receives the central office tape and delivers its output on fresh tape for use by the next machine, and so on until the last one delivers the end-products of the system.

The AMA Tape Reader

In order to "read" the data conveyed by the patterns of holes on the central office or other AMA tapes, the accounting center machinery needs first of all a "tape reader." The basic features of this reader are illustrated on Figure 12, and Figure 13 is an illustration of the device.

The reader has the same cylindrical drum as the perforator, with the lengthwise rows of 28 holes and the 0.1-inch circumferential separation between these rows of holes. There is thus a hole in the drum for every possible perforation in the AMA tape. The tape is wrapped partially around the drum for reading, and is "self-geared" with the drum by the spikes of the tape perforations. The drum can therefore move the tape forward step by step, bringing each row of tape holes into the reading position. The reading of the tape means, of course, a determination of which holes are per-

Figure 14 (left). Functional block diagram of AMA assembler

Figure 15 (right). AMA assembler

forated in each of the six digit-positions of a row. For this purpose the reader has a set of 28 thin blunt steel fingers mounted mechanically so as to form 28 feelers for holes. A tensioned spring pushes each of these steel fingers toward the drum. However, the fingers can only travel toward the drum as permitted by the contour of a restraining cam on a motor shaft. As this cam turns, and the steel fingers move toward the drum, those fingers finding a hole in the paper go through into the drum, while the other fingers are stopped in their motion by the paper. Each steel finger is mechanically coupled to a contact carrying detail, and the extra travel of the hole-finding fingers permits their respective contacts to close an electric circuit. The circuit closures in turn result in the operation of individual "reading relays." As the motor continues turning, the contour of the cam on its shaft soon forces all 28 steel fingers away from the drum, opening all contacts. Then the drum turns a tenth of an inch and a new row of tape holes is in position to be read. The motor driven cam now again permits the steel fingers to move toward the drum, and the reading cycle repeats. The reader is capable of going through this cyclic operation 16 times a second.

The AMA Assembler

A reel of central office AMA tape, 18 inches in diameter, contains the billing data for about 25,000 telephone calls. As brought out earlier, the call data are recorded as initial entries and conversation time-entries, each entry of a particular call being suitably labelled but sandwiched among entries of other calls. To permit computation of charges, the first step in the accounting center has to be used, therefore, to pick out and bring together the entries of each call. This is done by the assembler, a machine consisting basically of an input tape reader, a relay circuit of about 350 relays, and ten output recording perforators. Figure 14 is a functional block diagram of this machine and Figure 15 is an illustration of it.

The design of the assembler is based on the fact that the labelled entries of each call are recorded on the central office tape in chronological order. This order insures that, if there is on the central office tape an initial entry labelled, say, 32, the next time-entry on the tape with the label of 32 must be the answer-time entry of the same call, irrespective of the number of entries with other labels sandwiched in-between. It further follows that another succeeding time-entry with the label of 32 is the disconnect-time entry of the same call, no matter how far along the tape it was recorded. The label 32 is used, of course, subsequently for entries of other calls. However, as long as the sequence of the over-all record is not at all disturbed, (and this is a natural result of the tape recording technique) each initial entry serves as a new starting point for associating the next set of identically labelled time-entries.

Thus, the assembler's job is basically to sort the call entries according to their labels, without disturbing in any way their chronological order. Since the labels are two digit numbers, from 00 to 99, the sorting is done in two stages. First, the entries are sorted by the "units" digit of their label. If this digit is, say, 0, the entry is copied on the output tape of the 0 perforator. If the unit digit of the label is, say, 1, the entry is copied on the output tape of the number 1 perforator; and so on. The 0 to 9 output tapes gradually accumulate in their respective receiving bins. When the machine's operation is finished, these tapes are collected, spliced end to end, and reintroduced into the machine for sorting by the "tens" digit of the entry labels. As a result of this second sorting operation, the initial entry, answer time entry, and disconnect time entry of a particular call appear adjacent to one another on the appropriate one of the ten output tapes.

The physical operation of the assembler is, very briefly, as follows: First, by means of manually-controlled multi-position switches, the operator sets the machine to process the dated tape of a given central office recorder group. Then the machine is started and a few inches of splice pattern is perforated at the beginning of all ten output tapes. While the machine is doing this line by line, the operator inserts into the reader the beginning of the central office reel of tape made by the first recorder, using the splice pattern of this tape to engage the tape with the reader's drum. Then the operator signals the machine (by means of a key) to proceed with the sorting operation and leaves the machine. The

Figure 16. Functional block diagram of AMA computer

machine skips over the remaining splice pattern of the central office tape, until it comes to the tape identification rows of holes, containing the central office identity, the month and date of the tape, the recorder number, and so forth. The assembler matches the information in these rows of holes against its switch settings. If there is full agreement, indicating that the correct tape has been inserted, the machine proceeds to perforate identification information on its own output tapes. Then the machine sorts the individual call entries, pulling the input tape off the reel.

When the last call-entry has been reperforated on the appropriate output tape, and the end of the first recorder's tape runs out of the reader, the machine stops and signals the operator by sounding a chime signal. The operator now restarts the machine with the second recorder's tape. The machine checks the identity of this tape and then continues with its assembling operation. When the machine stops at the end of the last recorder tape, the operator signals it to perforate end-of-tape pattern on all its output tapes. Then, by pushing a key, the operator automatically cuts the ten output tapes, for removal to the splicing table.

What has been described is the simple, straight-forward working of the assembler performed at the rate of approximately 1,000 input tape lines per minute. The commercial version of the assembler has various complications superimposed on its basic functions. For example, the central office record of "every hour on the hour" has to be recognized by the assembler and appropriately associated with the call-entries; various erasure or skip orders received on the central office tape have to be recognized and obeyed; all central office recorders have to be serially accounted for; nonbillable test calls need be spotted and eliminated; central office trouble codes have to be interpreted and associated with calls affected; and so on. These features are, of course, in addition to the regular checking features woven throughout the AMA system.

The Computer

The ten output tapes of the second assembling stage—spliced together end to end and reeled—are fed daily into the reader of the next accounting center processing machine, which is the computer. This machine has, in addition to its input tape reader, a complex circuit of about 1,200 relays, and a number of perforators for recording the machine's output. Figure 16 is a functional block diagram of this machine.

The computer has several major functions. As its name suggests, its most basic function is to make computations. First, it calculates the conversation time of each completed call by subtracting the answer time from the disconnect time. Then it deducts a small fixed allowance to compensate for central office recording variations. The net conversation time is next rounded out to whole minutes, because telephone messages are charged for on the basis of minutes. This value of chargeable time is perforated on the output tapes of the computer for toll messages.

On bulk-billed messages, the computer makes additional calculations. It determines the message unit value of each such call, taking into account the chargeable time and the four parameters of the rate treatment applicable to the call. The message value is perforated by the computer on its output tapes of bulk-billed calls.

A second major function of the computer is to segregate the calls into different categories for facilitating subsequent processing. For example, as implied before, toll calls are segregated from local calls and both are perforated on separate output tapes. Another separate category is incompleted calls (calls that were not answered, and those that encountered a "line busy" condition). Such calls are simply discarded by the computer. Still another category is the message unit detail type calls. These are calls which are bulk-billed, but on which certain billing details are recorded and preserved for use by the business office

Figure 17. Functional block diagram of AMA summarizer

Figure 18. Functional block diagram of AMA printer

of the telephone company. This type of message has to be perforated by the computer on two output tapes: first, as any other local message on the regular bulk-billed tape, and then on a separate reference tape to preserve the appropriate details.

There are still other categories of calls. For example, if a subscriber questions service accounting accuracy, his line is temporarily marked so that all his calls are recorded in detail. The computer perforates such calls both as normal local or toll calls on its regular billing tapes, as well as on an entirely separate observing tape, preserving the details of even incompleted calls.

The last category of calls segregated by the computer is the "straddle" calls. These are calls that were in progress at 3 a.m., when the central office tape was being automatically marked for cutting. When the tape is actually cut later in the morning for shipment to the accounting center, information recorded prior to the 3 a.m. mark is brought to the accounting center, but the remaining information on calls in progress at 3 a.m. remains in the central office. The computer recognizes such situations and perforates the partial information on a separate tape to be combined with the next day's business.

One more major function performed by the computer is to sort messages. For instance, bulk-billed messages from multi-unit central offices are sorted by the central office unit number, so that subsequent processing can be done for one unit at a time.

The computer is designed to be a very exacting machine. It accepts and processes only unquestionable information. It checks, of course, the input tape identities; for each call it verifies that the information received is no more nor less than is required; it checks the exact succession of central office hours and days; it takes appropriate action on calls affected by trouble codes from the central office; and so on.

Physically, the computer is operated in a manner similar to that described for the assembler, except that calls go through the machine only once.

The Sorter

At intervals, (generally at the end of each 3- or 5-day round) the computer's output tapes of one type are spliced into one long reeled piece, for processing by the sorter. The sorter is a machine similar to the assembler in physical makeup, in general functions, and in operation. It sorts the messages according to the telephone numbers of the calling subscribers. This sorting is, of course, a multistage operation, the machine being repeatedly reset to sort by the "units," "tens," "hundreds," and "thousands" digit of the telephone numbers. After each sorting stage, the 10-output tapes are spliced, reeled, and reintroduced into the machine via its reader. The final output of ten tapes has all the messages in ascending telephone number order. Separate sorting runs are made for the different categories of computer outputs.

The Summarizer

Following sorting, the tapes containing bulk-billed messages are fed into the reader of the fourth machine of the accounting center. This machine, the summarizer, is basically a high-speed adder and contains, in addition to the reader, about 600 relays and an output perforator. Its job is to add the message unit values of all the bulk-billed calls of each subscriber, and to perforate the total on

Figure 19. Section of AMA message unit summary list and its interpretation

Figure 20. AMA toll slip and its interpretation

its output tape. Figure 17 is a functional block diagram of this machine.

The summarizer memorizes the calling telephone number of the first message on the input tape, and puts the message units into its A input register. Since this is the first message, the A-sum register has no sum in it. The message units in the A input register are therefore transferred directly into the B-sum register. If the telephone number of the second message on the tape is the same, its message units are registered in the B input register. The total of the B input and B-sum registers is recorded in the A-sum register. The message units of the third call of the same subscriber are steered into the A-input register, and the new total is recorded in the B-sum register. The process of cumulative addition continues at the rate of 1,000 additions per minute, until the input tape comes to a message belonging to the next subscriber. At that time the machine perforates the first telephone number and the accumulated total of message units on its output tape. If the adding exceeds 1,000 message units, the machine perforates the telephone number and exactly 1,000 message units, then continues with the adding process of the remaining message units.

It is appropriate at this stage to bring out how the cumulative total of message units for more than one round is obtained. The method is as follows. The summary output tape from the first round is merged in the sorter with the message tapes of the second round. In this operation, the sorter treats each subscriber's first round summary simply as a single, relatively high value message. Therefore, when the sorted tapes of this second round are put through the summarizer, the new message unit total includes the first round summary with the messages of the second round. In the same manner, the summary of the first two rounds is merged with the individual messages of the third round, and so on, until the final round of the billing period is included.

The Printer

This is the last accounting center machine, and its output is the output of the present AMA system. The machine comprises a tape reader, a relay circuit of about 800 relays, and a teletypewriter. Figure 18 is a functional block diagram of this machine.

The printer's main functions are to read an input tape, translate its patterns of holes into letters and numbers, arrange these letters and numbers in meaningful groups, and type the information, one character at a time, with appropriate headings and spacings. The typing is done at the rate of 600 characters per minute.

The basic translation done by the printer is, of course, from the 2-out-of-5 hole patterns into equivalent decimal numbers. Supplementary translations

Figure 21. Flow chart of AMA accounting center processing

Figure 22. AMA accounting center—Philadelphia installation

from numbers into alphabetical characters are performed, for example, for month designations; that is, month number 12 is translated into DEC. The most flexible translation job in the printer is, however, used to obtain the called central office name for each detail billed message. A calling subscriber, for instance, dials the ADam 6 office in his home area as AD 6. Actually his dial pulses this office code as 236, and it is so recorded and processed on the AMA tape. The printer has to translate the 236 combination for this area back into AD 6. Furthermore, if the same subscriber dialed office code 236 of an adjacent area, the printer may have to translate it into CE 6, standing for CEntury 6. This multidigit flexible translating function of the printer is accomplished by an adaptation of the central office translator.

The two most important outputs of the printer (there are also others) are tailored, of course, to fit the billing methods of bulk-billed messages and of detail-billed or toll messages. Thus, for bulk-billed messages, the machine prints the message unit summary tape at the end of every round, thus making available the total message units of each subscriber accumulated since the last billing date. This information permits interim billing of subscribers who, for various reasons, may have to be billed prior to the end of the billing period, and it also satisfies the regular end-of-period billing requirements. The printed message unit summary list, one for each central office, tabulates the subscribers in convenient ascending order of their telephone numbers. Figure 19 is an illustration of this message unit summary list, with adequate explanatory information for its interpretation.

The toll messages are printed at the end of every round on one or more toll slips per subscriber. These slips show the required billing details of the subscriber's toll messages. One slip is sufficient for nine messages. These slips are automatically cut and stacked in the order of the calling telephone numbers. Figure 20 is an illustration of a single-message toll slip, with adequate explanatory information for its interpretation.

The printed message unit summary lists and the toll slips are the chief end-products of the present AMA system. Other products, of secondary importance, are: printed message unit detail slips, and service-observed call slips. All these end-products can be merged readily with other non-AMA billing items, such as operator prepared tickets, miscellaneous charges, and so forth, to be processed by present manual methods into toll service statements and subscriber bills.

Epilogue: Accounting Center Machinery

Figure 21 is a flow-chart of the accounting center processing, and Figure 22 shows a section of the Philadelphia installation. Like the central office AMA recording facilities, the units of this processing system are also truly intricate. To those who are not familiar with relay circuitry, a recitation of the machinery's various basic functions cannot convey an adequate picture of this intricacy. The fundamental cause of this intricacy lies in the simplicity of the circuit elements, such as relays, cold cathode tubes, and so forth, which, in themselves, can only satisfy one of two conditions, and the intelligent actions that are demanded from the circuitry interconnecting hundreds of such elements into cooperating aggregates.

As is evident even from the general description, the relay aggregates of the accounting center machines have to be capable of such intelligent actions as calculating, sorting, translating, comparing, and so forth.

Accuracy of the AMA System

There is one over-all characteristic of the AMA system which is both of paramount importance, as well as an indication of the amount of ingenuity, and thoroughness that went into its design. This characteristic is the "accuracy" of the system.

One of the official accuracy tests was made in July, 1949 on a commercial installation of the system in the Philadelphia area. The test conditions closely reflected normal operating and maintenance situations. The following is a quotation from the final report of the Committee in charge of the tests.

"The objectives of the tests were fully met. Six test runs were made from July 21 to July 26, inclusive, with a total of 38,198 AMA calls completed. There were no overcharges of any kind. The charges on three calls were lost, that is, undercharges occurred amounting to 0.78 per 10,000 messages or 0.0078 per cent. Two of these charge irregularities were on message unit messages and were introduced by circuit failures in the central office. Defective paper in the accounting center caused the loss of charges on one toll call . . . . ."

Future Development

The AMA system is a recent offshoot of control circuit technology, a technology which the Bell System has developed to an impressive extent for automatic telephone switching applications. Relay digital computing machines[3] form another relatively recent and related branch of the same technology. It is a technology with fundamental economic and philosophical implications, in that it mechanizes actions normally associated with logical thinking and intelligence. Great advances will be made in this field in the future, and the AMA system, as a specific branch, will both benefit by and contribute to that progress.

Discussion

C. M. Tomlinson (The Bell Telephone Company of Pennsylvania, Philadelphia, Pa.): The Bell Telephone Company of Pennsylvania has had the Automatic Message Accounting (AMA) system in operation since July 11, 1948, in the Media Number 5 crossbar office and the accounting center at Philadelphia. Since then seven more crossbar central offices with AMA have been placed in service in the Philadelphia metropolitan area, of both the Number 5 and Number 1 types. The accounting center is processing the tapes from these eight offices, from one office in the Pittsburgh area, and from three offices of the New Jersey Bell Telephone Company in Camden. The last-named service is temporary, and is being handled in Philadelphia only until New Jersey's center in Newark is finished. The completed messages processed now total about 1,250,000 per month.

The central office tapes are transported daily to the accounting center, by truck messenger from the Philadelphia region and by first-class mail from Pittsburgh. Processing is done on a 2-shift basis with four machine attendants, one supervisor, and a maintenance man for each shift.

The growing pains with this radically new system have been remarkably few. Our experience of over $1^1/_2$ years fully bears out the high accuracy of the system which had been indicated by the pre-cutover tests.

O. A. Friend (Bell Telephone Laboratories, New York, N. Y.): I would like to offer some observations on the Automatic Message Accounting (AMA) development so ably described by Mr. Meszar from the standpoint of how it fits into the pattern of forward-looking switching development in the Bell System.

Like the earlier developments of zone registration and automatic ticketing, intended for different fields of application, AMA is a tool for service measurement. It provides the means for billing subscribers for service based on the number of calls made, their distance, duration, and time of day.

It has the ability to record information in sufficient detail to permit billing calls individually, and takes advantage of the lesser information which is sufficient where bulk billing is adequate. The electrical methods used for the rapid and accurate transfer of information in the central office and in the accounting center machines are drawn largely from the techniques developed over the years in common-control switching systems and in the wartime developments of relay computers, which have earned an enviable reputation for reliability and accuracy.

AMA provides the recording means needed for extension of dialing. The conversion of local central offices to dial operation has gained pace since the war, and some 73 per cent of the Bell System telephones are now dial. Plans which have been widely discussed are being carried out for mechanizing the handling of long-distance calls in the form of operator toll dialing. The ability to record billing information paves the way for increasing the range of mechanized handling of calls to limits determined by commercial and engineering considerations.

The form of record is compact and flexible. It lends itself to mechanized accounting processes to the extent and in the forms that these prove advantageous.

The AMA system, like automatic ticketing, permits wide flexibility in rate treatment and billing practices. By broadening the field for operator and subscriber dialing beyond present limits, it will contribute substantially to improved speed and convenience of service.

A Frequency Response Method for Analyzing and Synthesizing Contactor Servomechanisms

RALPH J. KOCHENBURGER
ASSOCIATE AIEE

THIS paper introduces a procedure for synthesizing contactor servomechanisms in which the frequency response of the system is employed. In this respect it represents a radical departure from the techniques used previously to handle the analysis and synthesis of such discontinuous servomechanisms. While these earlier methods all involve step-by-step procedures based upon the transient response, the method proposed here permits the analysis and synthesis procedure to be determined from a knowledge of the response of the components to sinusoidal signals of various amplitudes and frequencies.

The successful application of the proposed method is based upon an approximation which is valid for most of the physical systems encountered in practice. This approximation permits the discontinuous contactor to be represented in terms of a linear describing function. The limitations imposed upon the use of this approximation are discussed in the paper.

Although the proposed method can be profitably applied to both the analysis and synthesis of contactor servomechanisms, it is the synthesis problem which is particularly facilitated by this approach. Instances are described in the paper where a synthesis procedure based on this method resulted in a selection of design constants which greatly enhanced the performance of a representative contactor servomechanism.

Servomechanisms and feed-back control systems in general, may be classified as either continuous types or discontinuous types. Most of the existing literature concerning feed-back systems deals only with the types in which control is continuous, particularly when problems of analysis and synthesis are discussed. The scarcity of published treatments dealing with systems in which control is discontinuous is due, in some part, to the difficulties encountered when such systems are subjected to a rigorous mathematical treatment. On the other hand, discontinuous controls represent a substantial number of the systems used in practice, and methods for analyzing and, still more important, synthesizing them would be of decided practical interest.

Figure 1 is a block diagram representing a simple feed-back control system. Such a system may be subdivided into the error-detecting means, the controller, and the servomotor and output-load combination as shown. It is assumed that a direct feed-back path is employed, and that no additional component need be introduced to represent dynamic factors which modify the feed-back signal. The case when such an additional component need be considered in the feedback can, however, be handled as well by the general method described here. The symbolism used to describe the input and output signals of the various components is indicated in Figure 1.

In the more familiar linear continuous systems, the relationship between the correction and error signals may be expressed as a continuous function. If the controller characteristic is plotted in terms of the quiescent response, or steady-state response to various nonvarying error signals, the relation between the correction signal D and the quiescent value of the error δ, called δ_q, may be plotted as in Figure 2(A). In discontinuous systems, this relationship cannot be expressed by such a continuous curve. In the discontinuous type of system discussed here, and specifically the contactor type of servomechanism, the D versus δ_q relationship is itself discontinuous, as shown in Figure 2(B). In other words, as the error of the system varies in some continuous manner, the correction signal applied to the servomotor varies in discrete jumps.

Figure 1. General form of single-loop servomechanism

Paper 50-44, recommended by the AIEE Committee on Feedback-Control Systems and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1950. Manuscript submitted October 26, 1949; made available for printing December 1, 1949.

RALPH J. KOCHENBURGER is with the University of Connecticut, Storrs, Conn.

The material described in this paper represents some of the results obtained as part of a doctoral thesis research program conducted by the author at the Massachusetts Institute of Technology. The aid of various members of the Electrical Engineering Department and Servomechanisms Laboratory staffs and of H. K. Weiss of the Aberdeen Proving Grounds is gratefully acknowledged. The suggestions and criticisms furnished by Dr. Gordon S. Brown, Director of the Servomechanisms Laboratory, in his capacity as thesis supervisor were particularly helpful. Acknowledgment is due to the United States Air Forces, Air Materiel Command, Armament Laboratory, Wright Field, who sponsored the project under which this work was done.

(a) CONTINUOUS SERVOMECHANISM

(b) CONTACTOR SERVOMECHANISM

Figure 2. Typical controller relations

The type of controller characteristic shown in Figure 2(B) is found in those systems which employ mechanically or hydraulically actuated electrical contactors, electromagnetic relays, electronic-control circuits of the trigger or flip-flop type, certain types of mechanical clutches, and some hydraulic and pneumatic valves. These devices are distinguished by an all-or-nothing characteristic. Their actual characteristics may be more complicated than shown, but will still possess the distinguishing feature of producing sudden jumps in the value of correction signal D. Because one of the most frequent applications of contactor servomechanisms involves electromagnetic relays, this general class is sometimes described as relay servomechanisms. Contactor servomechanisms have found widespread employment in both military and industrial fields. They frequently possess advantages over continuous types in economy of weight, bulk, complexity, and cost of control equipment. One of the major practical objections to their use has been the nonlinearity of the response relationship. Only the simplest versions have been amenable to analysis. It has been difficult to analyze their performance characteristics and to synthesize design constants and compensating networks which will provide a specified performance.

One of the earliest analyses of contactor-type servomechanisms was published by Hazen[1] in 1934. He employed the direct differential-equation method for analyzing performance and a number of characteristics peculiar to contactor types were demonstrated. This method becomes cumbersome when the system is at all complicated because a new equation must be established and solved for each switching cycle or correction interval initiated by the contactor.

The phase-plane method of analysis provided a simple graphical approach. This method has been employed by various authors[2,3] in connection with other forms of nonlinear systems. It was applied to contactor servomechanisms by Weiss[4] and MacColl[5] and the analyses of certain types of such servomechanisms were shown to be greatly facilitated. Unfortunately, the method is limited to systems possessing relatively few energy-storage elements. A recent AIEE paper by Kahn,[6] based on the differential-equation approach, proposes relatively simple graphical constructions to eliminate some of the computational labor associated with the analysis of such systems.

There are two basic disadvantages to these methods of treatment, which might be characterized as solutions in the time domain. One disadvantage is the great difficulty of treating systems of apparently elementary physical configuration which have only a few energy-storage elements. The second and more significant disadvantage from the standpoint

Figure 4. General form of contactor servomechanism

of usefulness is the fact that the methods are not directly adaptable to system synthesis.

It is the purpose of this paper to present an analysis and synthesis procedure in which the frequency response of the system is employed in a manner[7] analogous to its use with continuous servomechanisms. Results obtained by the method have been compared with those obtained by more cumbersome exact methods and with test data* and the agreement has been found sufficient for most engineering applications. The method is not limited by any inherent dynamic complexity, provided the system can be described by a control loop as shown in Figure 1. Furthermore, the proposed method is particularly adapted to synthesis and permits the selection of compensating networks suitable for the attainment of given performance requirements.

*The contactor servomechanism simulator used to obtain the test data was purposely slow to provide ease of measurement: the slow response indicated in the examples should not be considered as generally typical of contactor servomechanisms.

General Configuration of a Contactor Servomechanism

Figure 3 illustrates a typical contactor servomechanism for controlling angular position. In this example, the various signals are represented as voltage equivalents; that is, the voltage e_ε is an indication of the angular error ε. A simple lead-type compensating network is shown in this example.

The compensating network converts the error signal to a new form, here called the *control signal*, before application to the contactor means. When no compensating networks are employed, ε and C are identical. In almost all cases, the introduction of a suitable compensating network results in improved performance. Networks of mechanical, hydraulic, or electrical forms may be used. In the contactor servomechanism of Figure 3, the controller includes the compensating networks and the succeeding contactor means. This is illustrated again in Figure 4 as a general block diagram of a single-loop contactor servomechanism.

In some cases, compensating networks may be inserted between the contactor means and the servomotor. This is usually less practical than the arrangement shown in Figure 4 because of the

Figure 5 (below). Typical contactor characteristics

Figure 6 (right). Typical electrical phase-lead compensating networks for cascade insertion in control system

higher power level at which the network is operated. When the network is directly cascaded with the servomotor and appears after the contactor means, its characteristics are generally lumped with those of the servomotor for purposes of analysis.

The contactor may be considered as a discontinuous power amplifier. The relay shown in Figure 3 represents one particular type. The relationship between C and D might follow one of the characteristics shown in Figure 5. In these diagrams, symmetrical operation is assumed in that the corrective efforts associated with positive and negative correction are identical in magnitude. It is convenient to express the correction signal D in dimensionless units, assigning it the value $D=+1$ when positive correction is initiated by the contactor and causes the servomotor to increase the output θ_o and $D=-1$ when negative correction is initiated.

In Figure 5(A), a relationship is shown where the contactor will initiate either positive or negative correction, depending on the algebraic sign of the control signal C. In this case, the *inactive zone* or range of error within which no corrective effort arises is zero. In Figure 5(B) an inactive zone, C_Δ, is introduced and the control signal must have a magnitude greater than $C_\Delta/2$ before corrective effort is initiated; otherwise the correction signal will merely be expressed by $D=0$. An inactive zone may be unavoidable because of physical limitations, but often it is purposely introduced because it contributes to dynamic stability. A system using a contactor possessing the characteristic of Figure 5(A) will always oscillate about some equilibrium point while one having an inactive zone as in Figure 5(B) can be designed to remain in a state of rest when no significant disturbance is applied. Since the inactive zone represents the range of permissible error within which no corrective action is initiated, it should not be excessively large. On the other hand, there is no point in making it smaller than the accuracy requirements of the application might stipulate. One of the basic problems of system synthesis is the selection of compensating networks which will permit adequate dynamic stability for some specified range of inactive zone. This problem becomes more difficult as the specified range of inactive zone becomes smaller.

Many contactors possess a hysteresis effect. This means that the control signal necessary to initiate correction is greater than that necessary to cease correction. In the case of electromagnetic relays, for example, the coil current of an already-closed relay must usually be reduced to some value lower than that which originally caused the relay to close before the relay will reopen. Figure 5(C) illustrates the effect as designated by the symbol C_h.

It can be shown that a hysteresis effect generally adversely affects the dynamic stability.

More complicated types of contactor characteristics are met in practice; for example, nonsymmetrical corrective action, or multistep contactors. These will not be discussed in detail but the general method of treatment to be introduced is applicable to them as well.

The other components of the contactor servomechanism, as shown in Figures 3 and 4, are the servomotor and the error-detecting means. Both of these usually exist in essentially the same form as in continuous systems. In a contactor servomechanism, however, it is rarely necessary to design for continuously variable control of speed. This greatly simplifies the equipment.

Performance Criteria of a Contactor Servomechanism

The performance criteria of contactor servomechanisms are basically the same as for continuous types. Static accuracy is one of the major design considerations. It is the possible range of error which can exist when the servomechanism is in a state of rest and which will not be sufficient to initiate corrective action. The static accuracy is therefore met by keeping the range of the inactive zone within specified limits.

Dynamic accuracy defines the extent to which errors are minimized when the system is responding to a disturbance. Such errors are best minimized by designing a system that will possess adequate speed of response and relative stability.

Figure 7. Dimensionless representation of contactor characteristics (case involving both inactive zone and hysteresis)

Speed of response deals with the rapidity by which errors are reduced to a tolerable level following some disturbance. The fastest response may be obtained by:

1. Using a runaway velocity that is as large as the stability limitations and servomotor capabilities permit.
2. Having the frequencies associated with any damped transient oscillation as high as possible.
3. Having adequate degree of stability for transient oscillations of amplitude greater than the region of error tolerance.

Stability is the tendency of a system to approach an equilibrium condition without excessive oscillation. Absolute stability is descriptive of a system incapable of self-sustained oscillations. Degree of stability refers to the rate with which transient oscillations disappear after a disturbance. A distinction must be made between the stability requirements imposed on nonlinear systems and those imposed on linear types. For the former, continuous self-sustained oscillations of a small amplitude may be permissible. For the latter, the amplitude of any self-sustained oscillations would tend to increase to an undesirably high value.

For contactor servomechanisms, performance requirements may be met by specifying a range of inactive zone consistent with the static accuracy requirements and a runaway velocity consistent with the desired speed of response. Once these are chosen, the major problem remaining is the selection of components which will provide adequate stability. The remainder of this paper is devoted primarily to the problem of stability.

Mathematical Representation of Characteristics

Transfer Functions

The assumption commonly employed in the study of continuous servomechanisms, that all components possess linear characteristics, will be applied to all of the components of a contactor servomechanism except the contactor. Each of these linear components may then be described in terms of its transfer functions or ratios of output to input.

Servomotor Characteristics

The transfer function of the servomotor, designated as $G_s(s)$, is defined by the ratio

$$G_s(s)=\frac{\theta_o(s)}{D(s)} \tag{1}$$

where $\theta_o(s)$ and $D(s)$ are the Laplace transforms of the output $\theta_o(t)$ and the

Figure 8 (left). Relation of correction signal to control signal for a simple contactor with hysteresis

Figure 9 (right). Comparison—exact response of servomotor with that obtained from fundamental harmonic approximation

correction signal $D(t)$, subject to zero initial conditions. When the polynomials of the transfer function are factored, it will appear as

$$G_s(s)=\frac{\theta_o(s)}{D(s)}$$
$$=\frac{R(1+\tau_1 s)(1+\tau_2 s)\ldots}{s(1+T_1 s)(1+T_2 s)(1+T_3 s)\ldots}$$
units of output quantity (2)

The τ's and T's are time constants which may be either real or complex. Equation 2 applies to the most common form of servomotor which approaches the condition of a constant output rate of R output units per second. The quantity R is the runaway velocity for a given correction signal applied for a sufficiently long time. The linear factor s in the denominator of the transfer function represents a single-order pole at the origin of the complex s plane and identifies a system having a sustained rate for a constant input signal. The servomotor or equivalent may have other forms of transfer function; for example, in regulator applications, there may be no pole at the origin while, in other applications a higher-order pole may exist. Only transfer functions of the form given in equation 2 are treated herein although the method is generally applicable to any form.

The transfer function also might be described in terms of its steady-state response to various real frequencies by substituting the imaginary quantity $j\omega$ for the operator s ($\omega=2\pi f$=angular frequency).

Equation 2 then assumes the form

$$G_s(j\omega)=\frac{\theta_o(j\omega)}{D(j\omega)}$$
$$=\frac{R(1+j\omega\tau_1)(1+j\omega\tau_2)\ldots}{j\omega(1+j\omega T_1)(1+j\omega T_2)(1+j\omega T_3)\ldots} \quad (3)$$

One advantage of the frequency-function form is the fact that, when the component being considered is not practically subject to an analysis based upon its design constants, the complex transfer function $G(j\omega)$ may often be expressed in graphical form on the basis of actual tests. The method of analysis and synthesis to be described here possesses the advantage that such graphical data may be directly employed. It is not necessary to convert $G(j\omega)$ to an analytic form.

The type of servomotor and load combination shown in Figure 3 has an elementary transfer function if, for example, coulomb friction, armature reaction and armature inductance are neglected. In this case, $G_s(j\omega)$ becomes

$$G_s(j\omega)=\frac{R}{j\omega(1+j\omega T)} \quad (4)$$

where the relations for determining the runaway velocity R and the time constant T are given in Figure 3. For many engineering purposes, this simplified form of relationship is adequate for analysis and synthesis. Similar transfer functions arise in many other servomotors.

Compensating Networks

The characteristics of the compensating network may similarly be expressed in terms of a transfer function $G_c(j\omega)$ as

$$G_c(j\omega)=\frac{(1+j\omega\tau_a)(1+j\omega\tau_b)\ldots}{(1+j\omega T_a)(1+j\omega T_b)\ldots}=\frac{C(j\omega)}{\delta(j\omega)} \quad (5)$$

It will be noted that at zero frequency $G_c(j\omega)$ is unity. This is because both C and δ are expressed in units of the output quanity; C being described in terms of the equivalent value of δ under quiescent

Figure 10 (left). Plot of the fundamental harmonic transfer function g_D—simple contactor with hysteresis ratio h/Δ, for case of zero input velocity ($d\bar{s}/dt=0$) and zero load torque ($\theta_L=0$)

conditions. Any attenuation or amplification occurring within the controller is described in terms of its effect on the range of inactive zone. This range is the sole measure of the zero-frequency gain of the system.

Figure 6 shows two common forms of compensating network for producing a phase-lead effect. For these networks, the transfer functions are given by

$$G_e(j\omega)=\frac{1+j\omega\tau_2}{1+j\omega\frac{\tau_2}{\alpha}} \text{ network of Figure 6(A)} \quad (6)$$

and

$$G_e(j\omega)=\frac{1+2\zeta_1 j\left(\frac{\omega}{\omega_1}\right)-\left(\frac{\omega}{\omega_1}\right)^2}{1+2\zeta_2 j\left(\frac{\omega}{\omega_2}\right)-\left(\frac{\omega}{\omega_2}\right)^2}$$

network of Figure 6(B) (7)

where

ζ_1, ζ_2 = numerator and denominator damping ratios, respectively

ω_1, ω_2 = numerator and denominator resonant frequencies, respectively

In the network of Figure 6(A), called a simple phase-lead network, the transfer function given in equation 6 includes the attenuation factor α, computed as shown in the diagram. The higher the value of α the more effective phase-lead effect is obtained. However, a high value of α results in a relative increase in the transmission of high-frequency noise. Some engineering compromise concerning its value is therefore required in practice.

Since the phase-lead effect of the circuit shown in Figure 6(A) cannot exceed 90 degrees, it may be inadequate for some applications. The resonant lead network shown in Figure 6(B) may then be employed. Equation 7 represents the transfer function of this latter network. Examples will be given where the use of these compensating networks materially improve system performance.

The Over-all Loop Transfer Function

Since the components represented by G_s and G_e are essentially linear and have transfer functions which depend only upon the applied frequency, they are called the frequency-variant portions of the system. On the other hand, the contactor, considered as having no dynamic lag but having a discontinuous characteristic, is nonlinear and therefore dependent on signal amplitude. Any dynamic lag action occurring in a physical contactor is conveniently lumped with either the servomotor or compensating network. The contactor represents the amplitude-variant portion of the system, and its describing function G_D, although independent of frequency, is dependent upon the control signal C. Other nonlinear effects such as backlash may be treated similarly in terms of amplitude-variant describing functions.

The over-all loop transfer function $G(j\omega)$ or combined transfer function of all linear and frequency-variant components is particularly significant. With the arrangement shown in Figure 4, this would merely be

$$G(j\omega)=G_s(j\omega)G_e(j\omega)=\frac{C(j\omega)}{D(j\omega)}\,\theta_1=\text{constant}$$

$$=\text{loop transfer function} \quad (8)$$

It will be shown how the loop transfer function and the contactor describing function may be used together to determine the performance characteristics of the control system.

Dimensionless Notation

The mechanics of analyzing and synthesizing contactor servomechanisms are simplified and the results obtained acquire more general utility if a dimensionless form of notation is used. This procedure is employed in many engineering fields and the system of notation proposed here is an expansion and modification of that introduced by Weiss.[4]

As a first step select a convenient time base t_b seconds. Then divide all variables and constants having the dimensions of time by t_b in order to obtain the corresponding dimensionless value; for example, $\phi=t/t_b$ = elapsed time. A convenient time base is frequently obtained

Figure 11 (left). Inverse response-function loci for single-loop servomechanisms

Figure 12 (right). Inverse transfer-function loci for single-loop servomechanisms

Table I. Dimensional and Dimensionless Symbols Used

	Quantity	Dimensional Symbol	Units	Dimensionless Symbol
Time Units	Time base	t_b	Seconds	
	Elapsed time	t	Seconds	$\phi = t/t_b$
	Time derivative operator	$p = d/dt$	Seconds^{-1}	$\lambda = t_b p = d/d\phi$
	Applied angular frequency	ω	Seconds^{-1}	$u = \omega t_b$
Signals in Control System	Signal base	$B = Rt_b$	Output-Units	
	Output	θ_o	Output-Units	$\sigma = \theta_o/B$
	Input	θ_i	Output-Units	$\delta = \theta_i/B$
	Error	$\varepsilon = \theta_i - \theta_o$	Output-Units	$\varepsilon = \varepsilon/B = \delta - \sigma$
	Control signal	C	Output-Units	$c = C/B$
	Correction signal	D	Dimensionless	D (same)
System Properties	Runaway velocity	R	Output-Units / Seconds	Unity
	Inactive zone	C_Δ	Output-Units	$\Delta = C\Delta/B$
	Hysteresis range	C_h	Output-Units	$h = C_h/B$
	Transfer functions:			
	Of servomotor	$G_s = \frac{\theta_o}{D}$	Output-Units	$g_s = \frac{\sigma}{D}$
	Of compensating network	$G_c = \frac{C}{\varepsilon}$	Dimensionless	$g_c = \frac{c}{\varepsilon}$
	Over-all loop	$G = G_s G_c$	Output-Units	$g = g_s g_c$
	Describing function of contactor	G_D where $D = G_D(C)$		g_D where $D = g_D(c)$
	Transfer function properties:			
	Time constant			
	In numerator	τ	Seconds	$\rho = \frac{\tau}{t_b}$
	In denominator	T	Seconds	$\gamma = \frac{T}{t_b}$
	Natural frequency	$\omega_1, \omega_2, \ldots$	Seconds^{-1}	$u_1 = \omega_1 t_b,\ u_2 = \omega_2 t_b \ldots$
	Damping ratio associated with a natural frequency	$\zeta_1, \zeta_2, \ldots$	Dimensionless	$\zeta_1, \zeta_2 \ldots$ (same)
	Attentuation factor of a compensating network	α	Dimensionless	α (same)

by setting $t_b = |T_1|$, where T_1 is the smallest time constant of the servomotor. In equation 4, for example, the only time constant T is naturally the lowest and $t_b = T$.

The next step is to select an output signal base B. All signals, such as the output θ_o, are divided by B in order to obtain the dimensionless equivalents, for example, the dimensionless output is expressed as $\sigma = \theta_o/B$. The inactive zone and hysteresis ranges, C_Δ and C_h, are dimensionlessly expressed as: $\Delta = C_\Delta/B$, $h = C_h/B$. The most convenient signal base B is the product of the runaway velocity and the time base, namely Rt_b. Table I summarizes the dimensional and dimensionless notation used.

In dimensionless form, the transfer functions of the servomotor and compensating network given in equations 3 and 5 become

$$g_s(ju) = \frac{(1+ju\rho_1)(1+ju\rho_2)\ldots\ldots}{ju(1+ju\gamma_1)(1+ju\gamma_2)\ldots} \tag{3A}$$

$$g_c(ju) = \frac{(1+ju\rho_a)(1+ju\rho_b)\ldots\ldots}{(1+ju\gamma_a)(1+ju\gamma_b)\ldots\ldots} \tag{5A}$$

The transfer function of the simple second-order servomotor expressed in equation 4 now is

$$g_s(ju) = \frac{1}{ju(1+ju)} \tag{4A}$$

The simple lead-compensating network and the resonant lead-controller network shown in Figures 6(A) and 6(B) now have the following dimensionless forms

$$g_c(ju) = \frac{1+ju\rho_a}{1+ju\frac{\rho_a}{\alpha}} \tag{6A}$$

$$g_c(ju) = \frac{1+2\zeta_1 j\left(\frac{u}{u_1}\right)-\left(\frac{u}{u_1}\right)^2}{1+2\zeta_2 j\left(\frac{u}{u_2}\right)-\left(\frac{u}{u_2}\right)^2} \tag{7A}$$

The Frequency-Response Method of Analysis and Synthesis

The frequency-response method of analysis and synthesis has been found to be a practical means for treating essentially linear servomechanisms.[7,8,9] By this method it is possible to determine whether the system possesses absolute stability; that is, whether it is capable of maintaining self-sustained oscillations. By various rules-of-thumb, it also is possible to reach qualitative conclusions concerning the degree of stability which are adequate for most engineering purposes. This technique uses frequency loci arranged in various forms to suit the convenience of the user; the well-known polar-locus plots are one example.

In view of the successful application of the frequency-response method to linear systems, its application to contactor servomechanisms appears desirable. The nonlinear relationship describing the contactor operation has impeded such an application. In the preceding sections it was necessary to express this relationship in terms of a describing function; it could not be expressed in terms of a linear transfer function. The frequency-response method is therefore not applicable unless certain assumptions are made.

In order to determine whether an adaptation of the frequency-response method might not be applied, let it be assumed that a sinusoidal control signal is applied to a typical contactor. Suppose that the contactor has the more general characteristic shown in Figure 7. If the control signal c is of the form

$$c = c_0 + |c_1| \cos u\phi \tag{9}$$

the contactor will initiate a positive correction when $c = \Delta/2 + h/2$, cease correction when $c = \Delta/2 - h/2$, initiate negative correction when $c = -\Delta/2 - h/2$, and cease correction when $c = -\Delta/2 + h/2$. These instants of time are designated by the angles, $u\phi = \alpha_1 - \beta_1$, $= \alpha_1 + \beta_1$, $= \pi + \alpha_2 - \beta_2$, and $= \pi + \alpha_2 + \beta_2$, respectively. This is shown in Figure 8(A). The angles $2\beta_1$ and $2\beta_2$ represent the duration of the positive and negative pulses, respectively; the angles α_1 and α_2 represent the phase lags associated with the respective pulses.

Figure 8(B) shows the rectangular form of the resultant periodic correction signal

D. The broken-line relation plotted in Figure 8(B) shows the average or zero-frequency component D_0 and fundamental harmonic component D_1 of this rectangularly shaped signal. Higher harmonic components which contribute to the corners of the rectangular shape are not shown.

If the correction signal consisted only of D_0 and D_1, only sinusoidally varying signals would exist throughout the system when sinusoidal inputs were applied. The contactor would then appear as a quasi-linear transfer device in that it would operate as a linear amplifier for any given constant amplitude of control signal. It would not operate as a truly linear device because of the nonlinear relationship between input and output amplitudes. Considering the contactor as such a quasi-linear device will permit the frequency-response method to be used in determining the system stability for any given control signal amplitude. The approximation which permits the higher harmonic components to be neglected so that the quasi-linear representation of the contactor may be employed must now be justified.

Figure 9 shows the relative importance of the harmonic components of the signals in a typical contactor servomechanism. Figure 9(A) shows a typical rectangular correction signal resulting from a periodic control signal. Figure 9(B) represents the harmonic spectrum associated with this correction signal. It is assumed, for example, that the servomotor has the typical transfer function given in equation 4, and that the fundamental frequency of the control signal is designated by the relation $u=1$. Under these considerations, an exact determination of the resultant servomotor output σ obtained by a mathematical determination of the repeated transients, would appear as plotted by the solid-line curve of Figure 9(C). The harmonic distribution of this output signal is shown plotted in Figure 9(D). It may be seen that, while the original correction signal D possessed higher harmonic components of significant amplitudes (referring back to Figure 9(B), these higher harmonic components have relatively small amplitudes, compared with the fundamental, when measured as part of the output signal.

The minor importance of the role played by the higher harmonic components also is demonstrated by the broken-line curve of the output response in Figure 9(C). This curve, designated as σ_1, represents the output response which would have been obtained if only the average and fundamental components of the correction signal had been present. It may be seen that this latter response curve is a fairly good approximation of the exact response represented by the solid-line curve.

If the higher-harmonic components may be considered negligible as far as the output signal is concerned, their contribution to the error and control signals will generally have minor significance. This in turn tends to justify the original assumption of a truly sinusoidal control signal.

It is therefore proposed that the frequency-response method of analysis be used where the contactor characteristic is described in terms of a quasi-linear describing-function $\mathfrak{L}_D$ where the subscript *1* is used to indicate that the describing

function takes into account only the fundamental harmonic component. This function neglects the higher harmonics with the following justifications:

1. The normal frequency spectrum of a rectangular wave involves progressively smaller amplitudes for increasing orders of the harmonic components.

2. Most servomotors serve as effective low-pass filters and minimize the importance of the higher-harmonic components.

Justification (1) above is valid for most cases but becomes less applicable under conditions where the pulse widths associated with the correction signals are short compared with the duration of the intervals between pulses. A periodic impulse signal of zero pulse width has odd harmonic components of equal magnitudes. Justification (2) was demonstrated using the example of an elementary servomotor; more complicated servomotors should serve as still more effective low-pass filters. On the other hand, it is conceivable that when servomotors exhibit marked resonance effects, the validity of the approximation may suffer under certain conditions where one of the neglected harmonic components might have a frequency near resonance and its effect on performance might therefore be particularly prominent.

At any rate, the previously-mentioned approximation is proposed so that the frequency-response method can be employed. Some conclusions concerning the general accuracy of the method may be reached by the comparisons given herein between the results thus obtained with those obtained by more exact methods of computation or by actual test. It should be kept in mind that the method proposed is an engineering approximation and that, even in the case of the better-understood continuous linear servomechanisms, conclusions regarding stability that are accurate to within 10-20 per cent are frequently satisfactory.

The Quasi-Linear Representation of the Contactor Describing-Function

The contactor may be approximately represented in the manner just described and cases involving the application of constant rates of input change or constant load disturbances may be taken into account. This entails additional mathematical complication because the duration of positive and negative corrective pulses will differ ($\beta_1 \neq \beta_2$). For brevity, only the case where symmetrical corrective operation occurs ($\beta_1 = \beta_2$) will be discussed. This implies the condition of zero average load torque and zero average rate-of-change of input.

Under this latter condition, the input signal δ may be of the form

$$\delta = \delta_0 + \delta_1 \cos u\phi \tag{10}$$

In order to determine the relative stability of the system when subjected to such an input signal, only the steady-state response need be considered when the frequency-response method is employed. Under such steady-state conditions, since the average value of input is constant, the average value of the output σ_0 also is constant. This can be the case only if the average component of the correction signal D_0 is zero, since from equation 2, the presence of an average component of D would result in an integrating action because of the s factor in the numerator of $G_y(s)$ and a $D_0\phi$ term would appear in the corresponding time solution for the response. The assumed sinusoidal nature of the control signal was expressed by equation 9. The average value of D or D_0 is given by

$$D_0 = \frac{\beta_1 - \beta_2}{2\pi} \tag{11}$$

Since, for this case $D_0 = 0_0$, $\beta_1 = \beta_2$, and the operation is symmetrical. But, from the trigonometric relations shown in Figure 8

$$\beta_1 = \frac{1}{2}\left\{\cos^{-1}\left[\frac{\Delta - h - 2c_0}{2|c_1|}\right] + \cos^{-1}\left[\frac{\Delta + h - 2c_0}{2|c_1|}\right]\right\} \tag{12A}$$

$$\beta_2 = \frac{1}{2}\left\{\cos^{-1}\left[\frac{\Delta - h + 2c_0}{2|c_1|}\right] + \cos^{-1} \times \left[\frac{\Delta + h + 2c_0}{2|c_1|}\right]\right\} \tag{12B}$$

Since $\beta_1 = \beta_2$ the average value of control signal c_0 must be zero, in which case

$$\beta = \beta_1 = \beta_2 = \frac{1}{2}\left\{\cos^{-1}\left(\frac{\Delta - h}{2|c_1|}\right) + \cos^{-1}\left(\frac{\Delta + h}{2|c_1|}\right)\right\} \tag{13}$$

Similarly, the phase-lag angles α_1 and α_2 shown in Figure 8 will be equal and will be

$$\alpha = \alpha_1 = \alpha_2 = \frac{1}{2}\left\{\cos^{-1}\left(\frac{\Delta - h}{2|c_1|}\right) - \cos^{-1}\left(\frac{\Delta + h}{2|c_1|}\right)\right\} \tag{14}$$

The foregoing results indicate that, for the case of an input disturbance represented by equation 9 and with zero average load torque, there will be zero average component of control signal. This also is based on the original assumption that the contactor exerts equal amounts of positive and negative corrective effort. Therefore, c_0 is zero and equation 10 simply becomes

$$c = |c_1| \cos u\phi \tag{15}$$

Since any average component of the error δ or δ_e would result in a finite value of c_0, the average error for the condition just considered will be zero.

By means of a Fourier analysis of the rectangular corrective pulse shown in Figure 8, the fundamental harmonic component may be shown to be

$$D_1 = |D_1| \cos\left(u\phi + \underline{/D_1}\right) \tag{16A}$$

where

$$|D_1| = \frac{2}{\pi}\sqrt{\sin^2\beta_1 + \sin^2\beta_2 + 2\sin\beta_1\sin\beta_2 \times \cos(\alpha_1 - \alpha_2)} \tag{16B}$$

$$\underline{/D_1} = -\tan^{-1}\frac{\sin\alpha_1\sin\beta_1 + \sin\alpha_2\sin\beta_2}{\cos\alpha_1\sin\beta_1 + \cos\alpha_2\sin\beta_2} \tag{16C}$$

If the fact that $\alpha = \alpha_1 = \alpha_2$ and $\beta = \beta_1 = \beta_2$ is considered, these equations acquire the simpler form

$$|D_1| = \frac{4}{\pi}\sin\beta \tag{17A}$$

$$\underline{/D_1} = -\alpha \tag{17B}$$

where the values of α and β are given in equations 13 and 14.

The contactor describing function, g_{D_1} may now be expressed in a manner similar to that used to describe transfer functions of linear components, that is, as the mathematical ratio of the output and input quantities, or

$$g_{D_1} = \frac{D_1}{c_1} \tag{18A}$$

which is written in vector form as

$$g_{D_1} = \frac{|D_1|}{|c_1|}\,\underline{/D_1} = \frac{4}{\pi}\frac{\sin\beta}{|c_1|}\,\underline{/-\alpha} \tag{18B}$$

The above expression represents the describing function for the quasi-linear approximate equivalent of the contactor. The angles α and β given in equations 13 and 14 are functions of the inactive-zone range Δ, the hysteresis range h, and the control-signal amplitude $|c_1|$. The amplitude and phase angle associated with the function g_{D_1} may be conveniently plotted as a function of the ratio $|c_1|/\Delta$ for various ratios of the quantity h/Δ representing the hysteresis effect. This has been done in Figure 10.

Figure 10 shows the amplitude and phase angle associated with the contactor describing-function for various control-signal amplitudes and various conditions of contactor hysteresis. It may be noted

that the describing function is independent of the frequency u. However, a phase lag is involved because of the hysteresis effect. When the control amplitude $|c_1|$ is less than $(\Delta+h)/2$, it is insufficient to actuate the contactor and, as shown in the diagram, the magnitude of g_{D_1} remains zero.

Stability Criteria for Contactor Servomechanisms

In view of the approximation proposed, the contactor servomechanism may be considered as equivalent to a system involving all linear components if a single constant signal amplitude $|c_1|$ is considered at a time. Under these conditions the describing function g_{D_1} may be treated in the same manner as a conventional transfer function. The ratio of the output response of the servomechanism shown in Figure 4 to a sinusoidally varying control signal of some dimensionless frequency u and of fixed amplitude $|c_1|$ would then be given by

$$\sigma(ju)=g_{D_1}g(ju)\mathcal{E}(ju) \tag{19}$$

where

$$g(ju)=g_c(ju)g_e(ju)$$

$$=\text{loop transfer function}$$

The error by definition is

$$\mathcal{E}(ju)=\delta(ju)-\sigma(ju) \tag{20}$$

If equations 19 and 20 are combined, the response ratio is conveniently given in inverse form as

$$\frac{\delta}{\sigma}(ju)=\frac{g^{-1}(ju)+g_{D_1}}{g_D} \tag{21}$$

where

$$g^{-1}(ju)=\frac{1}{g(ju)}$$

A system having an inverse response ratio as in equation 21 will be stable if, for a polar locus of $\delta/\sigma(ju)$ drawn for the complete range of frequencies, $-\infty<u<+\infty$, the origin of the plot always appears to the left of this locus as the locus is traversed in the direction of increasing frequency. This criterion is merely a simplified version of the well-known Nyquist criteria for stability. It applies only to single-loop systems.

Since only the orientation of the locus with respect to the origin is of interest, the criterion given could be applied as well to a locus representing merely the numerator of equation 21. Therefore only the locus of $g^{-1}(ju)+g_{D_1}$ need be plotted, since the quantity g_{D_1} appearing in the denominator of equation 21 is independent of frequency and simply represents a scale factor. This has been done in constructing the typical locus of Figure 11. In this example Figure 11(A) represents a stable system which fulfills the criterion. On the other hand the case represented by Figure 11(B) is unstable.

In the case of the loci of $g^{-1}(ju)+g_{D_1}$ shown in Figure 11, the origin was the critical point whose location with respect to the locus determined stability. However, it is convenient to shift the coordinate axes along the vector g_{D_1}. These translated axes are shown as broken lines in Figure 11. In Figure 12, the coordinate axes have been translated in this fashion and the point which was formerly the origin is now the point Q located at the tip of the vector $-g_{D_1}$. If such translated axes are used, the stability criterion given may be revised as follows:

If a polar locus of the inverse-loop transfer function $g^{-1}(ju)$ is drawn over the range of frequencies, u, and if a critical point Q is located at the tip of the describing-function vector $-g_{D_1}$ the system will be stable provided the point Q always appears to the left of the locus as the latter is traversed from zero to infinite frequency. Figure 12 demonstrates the application of the above criterion.

The foregoing test for absolute stability may be made for any specified value of control-signal amplitude $|c_1|$. It might in fact be found that the system will be stable for some amplitudes and unstable for others. The location of the point Q is dependent on the value of $|c_1|$. In order to obtain a complete picture of the stability, it is necessary that a second locus be drawn connecting the points Q over the complete amplitude range being considered. This curve will be referred to as the amplitude locus to distinguish it from the frequency locus plotted for the function $g^{-1}(ju)$.

The amplitude locus is drawn by plotting the tips of the vector values of the function $-g_{D_1}$ and connecting them by a curve. The two loci are superposed on the same graph and their relative orientation determines the stability characteristics of the system.

Figure 13 is an example of the superposed loci. The frequency locus shown is that representing the simple-loop transfer function given by the equation

$$g(ju)=\frac{1}{ju(1+ju)} \text{ or } g^{-1}(ju)=ju(1+ju) \tag{22}$$

The amplitude locus of Figure 13 represents the contactor describing function under conditions of a zero-average input velocity ($\delta=0$) and zero-average load torque. It was obtained from Figure 10 and represents a hysteresis effect given by $h/\Delta=0.2$.

In the case shown in Figure 13, the two loci intersect at the amplitude $|c_1|=0.062$. From the criterion just given, operating points on the amplitude locus corresponding to lower values of $|c_1|$, $0.060<|c_1|<0.062$, are unstable. Oscillations existing at these amplitudes will result in a tendency for the amplitude to increase. Operating points corresponding to higher values of $|c_1|$, that is, $|c_1|>0.062$, are stable. Oscillations existing at these amplitudes will result in a tendency for the amplitude to decrease. At the intersection itself, where $|c_1|=0.062$, the oscillations will tend to be maintained at this amplitude because this intersection corresponds to the borderline condition of stability.

The intersection point of the two loci is described as an equilibrium point. Because of the fact that higher amplitudes of oscillation decrease and lower amplitudes increase, the system's operating point tends to converge at this equilibrium point, it is therefore described as a point of convergent equilibrium.

The graphical construction shown in Figure 13 indicates that any initial disturbance sufficient to initiate the contactor, that is, $|c_1|>0.060$, will result in oscillations which will approach a self-sustained condition with an amplitude and frequency corresponding to the intersection point of the two loci. Disturbances less than sufficient to trip the contactor are beyond the cut-off point of the amplitude locus, where $g_{D_1}=0$, and naturally no oscillations result.

From Figure 13, the self-sustained oscillations will correspond to a dimensionless control-signal amplitude of $|c_1|=0.062$ (the error amplitude is the same since $g_e=1$) and a dimensionless frequency ratio given by $u=3.1$. The graphical construction which provides this result depends upon the basic approximation mentioned previously. It is therefore interesting to compare the predicted result with that actually observed or computed by more exact methods. Such calculations show that the actual conditions of steady-state self-sustained oscillations would be given by $|c_1|=0.066$ and $u=3.2$. The agreements concerning amplitude and frequency are within $6^1/_2$ per cent and 3 per cent respectively.

Convergent and Divergent Equilibrium

The preceding section illustrated an intersection of loci that indicated a con-

Figure 17. Loci diagrams illustrating stability improvement resulting from use of a phase-lead compensating network

Figure 18. Loci plots for contactor servomechanism with critically damped servomotor

vergent condition of equilibrium. Figure 14 illustrates other possible configurations of the loci, some of which involve one or more intersections. In general, these intersections indicate convergent equilibrium if a slight increase in $|c_1|$ from its value at the intersection causes the locus of $-g_{D1}$ to enter the stable region and if a slight decrease causes it to enter the unstable region. In this event, self-sustained oscillations may result. If the intersections possess the converse properties, the equilibrium condition is divergent; it then does not correspond to a condition of self-sustained oscillation, but merely represents an amplitude boundary. The operating point will always tend to shift away from such a divergent equilibrium point. It may be noted from Figure 14 that the loci always intersect at the origin, corresponding to the condition that $|c_1| \to \infty$ and $u \to 0$. The origin equilibrium points are divergent in Figures 14(A), (C), and (E) and the amplitude of any oscillations which might arise will tend to decrease until either a convergent equilibrium point is reached or the contactor cut-off point, as marked by the abrupt termination of the amplitude locus is reached. The origin equilibrium points in Figures 14(B), (D), and (F) are convergent, indicating that if these systems are subjected to disturbances of sufficient magnitude, destructive oscillations will result.

It also might be noted that, in Figure 10, the amplitude of g_{D1} is plotted in terms of the quantity Δg_{D1}. This function is therefore inversely proportional to Δ for a given amplitude ratio $|c_1|/\Delta$. The inactive-zone range Δ appears as a reciprocal scale factor affecting the amplitude locus. The scale of this locus may be varied by changing the inactive-zone range, and the stability characteristics of the system may thus be altered. In the cases shown in Figures 13 and 14(A) and (E), the response can always be made stable for all conditions of operation by making the inactive-zone sufficiently large.

Degree of Stability

In many applications of contactor systems, a specification that requires merely a stable system is inadequate. The requirement that any transient oscillation following the correction of disturbance shall involve sufficient damping also is imposed. In other words the degree of stability is of importance.

In the case of linear servomechanisms, a rule-of-thumb procedure has been developed[7] which gives an indication of the degree of stability from the frequency-response loci. This procedure is to determine the peak value M_p of the output-input ratio $M = |\theta_o/\theta_i| = |\sigma|/|\delta|$. In general, it is found that satisfactory damping exists if $M_p < 1.3$, the exact limit imposed depending upon the application. This rule-of-thumb method must be used with caution. When it is backed up by the designer's past experience, successful system designs are obtained.

It is proposed that a similar rule-of-thumb criterion be used to determine the degree of stability of contactor servomechanisms. Figures 15 and 16 show how this might be done. Figure 15 contains the two loci shown previously in Figure 13. However, the inactive-zone range has been increased to a value of $\Delta = 0.4$. Under this condition, the system will possess absolute stability, as shown by the fact that the loci do not intersect.

The peak ratio of output-to-input amplitudes M_p may be determined for a given control-signal amplitude $|c_1|$ by graphical means now to be described. Equation 21 may be inverted and rewritten as

$$\frac{\sigma}{\delta}(ju) = \frac{g_{D1}}{g^{-1}(ju) + g_{D1}} = \frac{\text{output}}{\text{input}} \tag{23}$$

In Figure 15 the quantity g_{D1} is represented by the vector QO and the quantity $g^{-1}(ju)$ by the vector OP. The sum appearing in the denominator of 23 will therefore be represented by the vector sum $(QO + OP)$ or by the connecting vector QP. The output-input ratio is therefore expressed by the vector ratio

$$\frac{\sigma}{\delta}(ju) = \frac{QO}{QP} \tag{24}$$

The amplitude ratio or value of M is merely

$$M = \left|\frac{\sigma}{\delta}(ju)\right| = \frac{\text{length of } QO \text{ vector}}{\text{length of } QP \text{ vector}} \tag{25}$$

For a given value of $|c_1|$ the vector length $|QO|$ is constant. Therefore M_p or the peak value of M over the frequency range is given by

$$M_p = \left|\frac{QO}{QP}\right|_{\min} = \frac{\text{length of } QO \text{ vector}}{\text{minimum length of } QP \text{ vector}} \tag{26}$$

The minimum length of the QP vector is found by drawing an arc of shortest possible radius, tangent to the frequency-response locus from the point Q as a center. The frequency u at the point of tangency of the $QP_{\min}$ vector with the frequency-variant locus is designated as the peak frequency u_p.

The values of M_p and u_p determined over the entire range of control-signal amplitude $|c_1|$ provide a complete picture of degree of stability. This is shown in Figure 16. For the case considered in the examples, the values of M_p and u_p increase

with a decrease in control-signal amplitude. This indicates that during the beginning of a correction process involving high control-signal amplitudes, the system would act as though it possessed adequate response damping and had a relatively low natural frequency. On the other hand, as the correction process approached completion, the degree of stability would become poor and the frequency associated with the transient oscillations would increase. This is a common characteristic of uncompensated contactor servomechanisms. When an actual servomechanism having the properties represented by Figures 15 and 16 was subjected to a large disturbance, the initial correction process appeared well damped but slow with a moderate initial overshoot, but the final portion of the correction process appeared poorly damped but more rapid. Eight positive and eight negative corrective impulses were initiated by the contactor before the correction process ceased and the error finally remained within the inactive zone.

The foregoing example represents a servomechanism possessing a low degree of stability, as evidenced by the value of M_p approaching 4.5 before the cut-off point is reached. It has been found from experimental tests on various types of contactor systems that an M_p of 2.0 near the cut-off point and of 1.3 for higher control-signal amplitudes provides a satisfactory degree of relative stability for most applications.

In the example shown, the degree of stability was poor in spite of the large inactive zone. It is obvious that compensating networks are desirable to improve the response in even the most elementary types of contactor servomechanisms.

Application of a Simple Phase-Lead Type Compensating Network

The example in the preceding section involved a low degree of stability in spite of the large inactive zone employed ($\Delta=0.4$). In most practical applications, a smaller inactive zone would be specified because of accuracy considerations and a typical value might be given by: $\Delta=0.05$. In that case, the amplitude locus would appear as in Figure 17. The uncompensated frequency locus is the same as in the preceding example. Because of the decrease in Δ, the loci intersect and self-sustained oscillations occur. The point of intersection indicates that these oscillations involve a control-signal amplitude $|c_1|=0.74\Delta=0.35$, at a frequency $u=4.70$. Experimental tests indicate that the control-signal amplitude of oscillation (which also equals the error and output amplitudes since no compensation is assumed) is given by $|c_1|=0.040$ at a measured frequency $u=4.30$. The discrepancy between calculated values and test values is only 12 and 10 per cent, respectively.

A compensating network of the form shown in Figure 6(A) was employed to improve stability. An attenuation factor $\alpha=10$ was specified since this represents a practical compromise between the problem of obtaining a large phase lead and that of minimizing the amplification of noise signals. Plotting loci curves corresponding to various trial values of the time constant ratio ρ_a, given in equation 6A shows that the best stability characteristics are obtained when $\rho_a=0.3$. The dimensionless transfer function of the compensating network is then

$$g_c(ju)=\frac{1+0.3ju}{1+0.03ju} \tag{27}$$

The compensated frequency locus shown in Figure 17 is based on the network of equation 27. The frequency and amplitude loci no longer intersect and self-sustained oscillations will not occur. Furthermore, if the rule-of-thumb criterion for degree of stability is used as described previously, the value of M_p is a maximum when the control-signal amplitude $|c_1|$ is just at the cut-off point and is given by $M_{p\max}=1.76$. In view of the previous discussion on degree of stability, the compensated system should be adequately stable.

An experimental version of this servomechanism confirmed the results predicted above. The test equipment involved a runaway velocity R of 30 degrees per second and a time constant T of 2.3 seconds, giving a signal base of the dimensionless notation as $B=RT=69$ degrees. The actual inactive zone was 3.5 degrees (or $\Delta=C_\Delta/B=3.5/69=0.05$). The compensating network had a numerator time constant τ_a of equation 6 given by $\tau_a=\rho_a\rho_b=\rho_a T=0.3\times 2.30=0.69$ seconds. The electrical constants for the network of Figure 6(A) are $R_0=4{,}000$ ohms, $R_1=1.45$ megohms, $R_2=157{,}000$ ohms, and $C_1=1.0$ microfarad. When this compensating network was used, a sudden input change of 360 degrees resulted in an initial error overshoot of 15 degrees and then an undershoot of two degrees. The error then remained within the inactive-zone range. Such a response would be considered to have adequate degree of stability for most applications.

This experimental test not only confirmed the conclusions reached from the loci diagram, but also demonstrated that the addition of the compensating network resulted in a spectacular improvement in the transient response. It is interesting to note that the optimum value of the numerator time constant $\tau_a=0.69$ seconds selected on the basis of the loci diagram was also the optimum when experimentally selected by trial-and-error means.

Application of a Resonant Phase-Lead Type of Compensating Network

A contactor servomechanism possessing more complicated dynamic characteristics has also been investigated. The servomotor transfer function corresponding to equation 3 was

$$G_s(ju)=\frac{30}{ju(1+2.3ju)^2}\text{ degrees} \tag{28}$$

The runaway velocity was $R=30$ degrees per second as before. The basic time constant was again $T=2.30$ seconds. However, the transfer-function term involving the time constant is now second order and the servomotor response is critically damped. The dimensionless transfer function of the servomotor then is reduced to

$$g_s(ju)=\frac{1}{ju(1+ju)^2} \tag{29}$$

The uncompensated frequency locus in Figure 18 corresponds to the loop transfer function of the servomechanism without the compensating network. The amplitude loci curve of Figure 18 corresponds to a contactor inactive-zone range of $\Delta=0.07$ and a hysteresis effect given by $h=0.03\ \Delta=0.021$. This ratio of h to Δ represents a typical practical minimum for many applications. The two loci intersect at a value of control-signal amplitude $|c_1|=9.5\Delta=0.66$ which is relatively large. This would correspond to self-sustained oscillations with an error amplitude of 46 degrees. It would be necessary to increase the inactive-zone range to an impractically high value $\Delta=0.63$ or a static error range of $\pm B\Delta/2=\pm 69\times 0.63/2=\pm 22$ degrees in order to suppress these oscillations. The need for a compensating network is obvious.

Trial constructions of loci indicated that suitable compensation was not obtainable with a simple lead controller of the type shown in Figure 6(A). A resonant lead network similar to that shown in Figure 6(B) was therefore used.* The

*The actual compensating network possessed the same characteristics as that of Figure 6(B); however, a circuit arrangement employing electronic feedback was used. This was done in order to avoid the use of the impractically high values of inductance and capacitance which would otherwise have been required.

characteristics were selected by trial-and-error, graphical constructions of the frequency locus being employed. It was found that a resonant lead controller having a transfer function of the form stated in equations 7 and 7A provided the best response with the following constants

$$\zeta_1 = 0.6 \qquad \zeta_2 = 0.6$$

$$u_1 = 2 \qquad u_2 = 6.3$$

$$\omega_1 = \frac{u_1}{t_b} = 0.87 \frac{\text{radians}}{\text{second}} \qquad \omega_2 = \frac{u_2}{t_b} = 2.76 \frac{\text{radians}}{\text{second}}$$

$$\text{attenuation constant } \frac{\omega_2^2}{\omega_1^2} = 10$$

With a compensating network of this type the frequency-response curve is that described as the compensated-frequency locus in Figure 18. Since no intersections of the amplitude and frequency loci occur, the system is stable. The maximum value of M_p is determined graphically as $M_{pmax} = 2.5$. This value is somewhat higher than that specified previously but indicates that a reasonable degree of relative stability might be expected.

Experimental tests incorporating this compensating network with a critically damped servomotor having a transfer function of the form given in equation 29 were conducted. The transient response appeared satisfactory. A sudden input change of 360 degrees resulted in an initial error overshoot of 27 degrees, a subsequent undershoot of 13 degrees, an overshoot of seven degrees, and then an undershoot of two degrees before the correction process was completed. The total correction process described involved a time interval of 37 seconds; half of this time involved the initial correction process prior to the first overshoot when the speed of response is limited by the value of runaway velocity. In view of the inherently slow response of the servomotor (purposely made so to provide ease of measurement), the performance may be considered satisfactory.

The results described above corresponded to an inactive-zone range of 4.6 degrees ($\Delta = 0.07$). From Figure 18, a reduction in the inactive-zone range to a value given by $\delta_\Delta = 2.5$ degrees ($\Delta = 0.038$) would be just sufficient to cause the two loci curves to intersect and self-sustained oscillations to result. This change in inactive zone would be represented by a simple increase in the scale of the amplitude loci curve by the factor 0.07/0.038. The loci curves indicate that these oscillations would have a frequency given by $u = 5.9$ or $\omega = ut_b = 2.56$ radians per second or a period of $2\pi/\omega = 2.45$ seconds, and a control-signal amplitude given by $|\epsilon_1| = 0.027$. The corresponding dimensional error amplitude would be $|\delta| = B|\epsilon_1|/g_c(j5.9) = 0.76$ degrees.

Actual tests indicated that it was necessary to reduce the inactive-zone range to a value of $\delta_\Delta = 2.7$ degrees before self-sustained oscillations could occur. This is within 8 per cent of the predicted value of 2.5 degrees. The observed period of oscillation was 2.7 seconds, or 10 per cent longer than the predicted value of 2.45 seconds, and the error amplitude was 3/4 degree or equal to the predicted value of 0.76 degrees as closely as could be determined in view of the accuracy of measurement.

The condition of self-sustained oscillations obtained with the smaller inactive zone might be acceptable for some applications of contactor servomechanisms. On the other hand if the application's specifications prohibit such oscillations, an 80 per cent increase in inactive-zone range would provide the reasonably well-damped transient response described previously. It is to be noted that the error amplitude associated with self-sustained oscillations can be considerably smaller than the inactive-zone range when a phase-lead type compensating network is employed.

The effectiveness of the compensating network is best demonstrated by the fact that, in the case of the uncompensated system, an inactive-zone range given by $\Delta = 0.63$ was required to prevent the occurrence of excessive self-sustained oscillations. With the addition of the compensating network an inactive-zone range of $\Delta = 0.038$ was sufficient to prevent oscillation. This is a permissible improvement in static accuracy by a factor of seventeen.

Experimental Verification of the Theory

The examples previously mentioned represented several cases where the predicted performance was compared with that obtained by actual experimental tests. These tests were performed on a model of a contactor servomechanism designed to simulate actual systems. This simulator employed a shunt-type d-c motor as the servomotor and operated essentially as shown by Figure 3. The actual circuit details were, however, considerably more complicated than shown in that diagram. Various adjustable dynamic characteristics and contactor characteristics were provided and extraneous factors which might lead to incorrect results were minimized by suitable design. The simulator was designed so that the inactive-zone range and hysteresis range could be adjusted, so that the servomotor transfer function could assume varied forms including those involving finite time delays, and so that various compensating networks could be introduced. The details of construction of this device and that of the electronic-feedback type resonant-lead controller mentioned in the preceding section are not discussed here since they are not directly pertinent to the subject matter.

The instances given where the results predicted by the theory were compared with experimentally observed data represent only several examples of a large number of such tests made for various types of contactor servomechanism problems. In general, the percentage agreement was the same as shown in these examples. It was considered desirable that the results obtained by the simulator be of a form which could be visually recorded so that electrical recording instruments would not generally be required. For this reason, the relatively slow runaway velocity of 30 degrees per second and the basic time constant of 2.30 seconds were chosen. By employing proper scale factors, faster servomechanisms may still be represented by the simulator. The purposely slow response of the simulator should be kept in mind when evaluating the results described in the preceding sections; the dimensional performance figures given are not necessarily typical.

Conclusions

The investigation described in this paper leads to the following basic conclusions:

A frequency-response method of analysis and synthesis may be adapted to contactor servomechanisms by employing a simple approximation. This method is usually capable of providing sufficiently accurate results for most engineering applications.

The performance of contactor servomechanisms can be materially improved, in even the simplest cases, by the introduction of suitable compensating networks. The proposed frequency-response method of treatment is particularly adaptable to the selection of such networks.

The approximate method of treatment used here in application to contactor servomechanisms also is generally applicable to the analysis and synthesis of other nonlinear systems. It might prove of particular value if the nonlinear effects, such as backlash, coulomb friction, saturation, and so forth, appearing in essentially linear servomechanisms were treated by this means. It is hoped that the technique introduced here will contribute to the more effective employment of contactor servomechanisms in control applications.

Discussion

George A. Philbrick (George A. Philbrick Researches, Boston, Mass.): Since many readers of this able and intelligent paper will not previously have come across its author, it is appropriate to mention an earlier, and unpublished, contribution by him. While working with the Propeller Division of Curtiss-Wright Corporation prior to 1946, Kochenburger prepared a skillful analysis of a compound automatic control problem in turbo-prop regulation. This analysis was happily received and applied in a related project by the present writer

The paper under discussion treats a fundamentally nonlinear servomechanism, which it appears to handle successfully by a harmonic method. It will thus give great comfort to frequency enthusiasts. If some of the comments which follow are at best dispassionate, attribute them to the fact that this writer is an enthusiast from another camp altogether.

Items which it is felt belong in the list of references include a paper by A. Ivanoff;[1] and the recently translated book, Dynamics of Automatic Control, by Oldenbourg and Sartorius.[2] Ivanoff studied the combined influences of inertness and static friction, under sinusoidal performance, in a manner related to the Kochenburger approach; the compensatory effects of inertness, for example, were clearly shown by him. In the Oldenbourg book, which contains many pioneering elements, similar nonlinear phenomena also are introduced into otherwise linear control loops, and the stability and performance evaluated through consideration of the behavior of the fundamental frequency, as is done in the present paper. A recent noteworthy paper in this same field was prepared by T. A. Rogers of the University of California.[3]

A more serious omission, from the writer's point of view, is the absence of any reference to the method of analogy as a tool of analysis and synthesis in the study of systems of this general type. The current availability of analogue computing components, as a concrete fact, requires the qualification, even the revision, of many of the statements in the paper. Such components are regularly employed in our laboratory, and elsewhere, to represent regulatory systems of which those described in this paper form a special case. In a few minutes after receipt of this paper the first example described was set up, operated, and the conclusions corroborated quantitatively through oscilloscope displays. The computing assemblage is shown in Figure 1 of the discussion. Straightforward additions lead to the second and slightly more involved example. All the components exhibited are perfectly standard catalog items.

An interesting outcome of our brief experience with the analog representation of this problem was the observation that substantially the same compensating characteristic is optimum when the nonlinear contactor-unit is replaced by the simplest linear approximation. As to the form of the time responses themselves, which are important for many applications, all will agree that these do not come readily from any frequency method. The analog of course, on the other hand, gives time responses directly for either discrete or random stimuli, and frequency responses as well for those who want them. In a more intricate nonlinear control or servo system, of which perhaps the mechanism discussed is a minor component, the applicability of the author's approach may be open to some additional doubt, whereas the abilities of the analog are inherently unaffected by the extent or complexity of the primary structure under study.

Figure 1. Analog computing assembly for the contactor servomechanism

Ralph J. Kochenburger: The author appreciates the constructive comments made by Mr. Philbrick in his discussion of this paper and wishes to thank him for calling attention to an earlier unpublished work in the field of feedback control systems. Several interesting points were raised in his discussion which warrant further clarification.

Mr. Philbrick classifies this paper as belonging to the "camp of frequency-response enthusiasts." There has been an unfortunate tendency to group engineers studying feedback control systems into two groups those interested in the transient response of such systems and those interested in the frequency response. Such a distinction is fallacious since all of these engineers are interested in the transient response of the system they are studying. It however happens that, in complicated feedback control systems, the operational calculus necessary for a direct approach involves computations which become unduly cumbersome and the seemingly "round-about" method of first studying the response of the system to sinusoidal disturbances and then predicting the transient response from these results represents a more practical approach. This is particularly the case when the system contains components whose input-output relationships are not readily subject to analytic representations but which can be described in terms of experimentally derived data.

It might be kept in mind that the Nyquist criteria, upon which the frequency response method is based, are no more than means for determining whether any objectionable terms exist in the transient response relationship. In its most frequently applied form, the locus of the transfer function is plotted for various values of "real frequency," that is, the substitution is made that $s = j\omega$ where s is the Laplace transformation operator. This form permits the question to be answered—is the system stable? It is however possible to use this general method to determine how stable the system is as well. If it is not only specified that it be stable but that its response involve no oscillatory components with damping ratios less than some specified value, ζ, it is merely necessary to draw a new transfer locus using the substitution, $s = \zeta\omega_n + j\sqrt{1-\zeta^2}\omega_n$ over the complete range of frequencies, ω_n, and then to apply the same graphical test as before. If the criteria are fulfilled for such a complex frequency locus, then all damping ratios involved in the response function will be greater than the

specified value ζ. Sometimes this second procedure is tedious and for this reason the engineer frequently determines the response function for the range of real frequencies only and then employs various well known rules-of-thumb to make approximate predictions covering the nature of the transient response.

Mr. Philbrick mentions two earlier contributions where other problems in nonlinear dynamics employ a similar approximation by which all but the average and fundamental frequency components of a nonsinusoidal periodic function are ignored. Such an approximation method has been used frequently and is generally well-known. The author consequently did not cite all of the contributions where such a procedure is employed. The paper under discussion merely suggests a combination of this procedure and of the Nyquist method which is particularly applicable to nonlinear servomechanisms. The reference given in the discussion to a recent paper by T. A. Rogers is of particular interest. The author has not yet had the opportunity to examine this contribution.

The discussion points out the omission of the analogue method for studying feedback control systems. The author agrees that this method should have been accorded more emphasis since it constitutes a practical means of attack in many instances. As a matter of fact, mention was made in the paper of a simulator or analogue device employed by the author to check the validity of the proposed method in the case of several specific problems. It is felt that the analytic and analogue approaches complement each other and that there is need for both in control system design. The analytic approach has an advantage in that it not only determines the nature of the response itself, but also shows which design factors are the cause of its various features. It consequently gives direct information leading to the synthesis of an improved system.

Analogue methods show the nature of the system response but the synthesis problem still involves a trial-and-error variation of design constants. Furthermore, the experimental facilities involved in such an approach may be expensive. Their use may well be justified in a laboratory dealing with a number of related control problems. In the case of industrial concerns which encounter problems in feedback control systems at only infrequent intervals, there is some question regarding their economic justification.

It is appreciated that Mr. Philbrick used his analogue computor to check some of the results presented in the paper. More quantitative information concerning the correlation of the two methods would have been of interest.

The discussion mentions that a prediction of the time response does not come readily from a frequency response method. Methods by which the general nature of the time response can be predicted from a knowledge of the frequency response have been mentioned. If an actual picture of the time response is desired, this too may be obtained by a method developed by Dr. George W. Floyd and described in Chapter 11 of reference 1 of the paper. In regard to elements of doubt regarding the applicability of the proposed method to more involved systems, it is true that, in view of space limitation, the paper discussed only the application to a basic single loop system. An extension of this method applicable to a multiloop system should follow directly and also should be valid provided the Nyquist criteria are correctly applied. The simple form of these criteria given in the paper holds only for single-loop systems with stable components. In any case, some check should be made in any given problem concerning the validity of the approximation upon which this method is based.

In conclusion, the author wishes to thank Mr. Philbrick for his discussion and for the number of interesting suggestions he has made.

Phase Lead for A-C Servo Systems with Compensation for Carrier Frequency Changes

ARTHUR P. NOTTHOFF, JR.
STUDENT MEMBER AIEE

THE basis for operation of a feedback-control system lies in the comparison of the output quantity with the input quantity. The equipment used to compare information contained in these two quantities comprises the data-transmission and error-measuring system. It is frequently convenient to transmit this information by means of an a-c signal whose envelope is at all times proportional to the error, and whose phase is determined by the sign (or sense) of the data signal, that is, data are transmitted as a suppressed carrier modulated signal. If, in addition, the signal which controls the system output member is an a-c signal, the system will be defined as an a-c system, as illustrated in Figure 1.

It has been demonstrated elsewhere[1] that networks which impart a phase lead to the error-data signal may be used to improve static and/or dynamic system performance. Phase lead for an a-c system may be introduced by either of the following basic techniques:

1. The modulated error signal, V_4, is demodulated, phase lead is introduced at a d-c level, and the resultant signal is remodulated to produce the control signal, V_1.
2. V_4 is impressed upon a network which operates upon the carrier frequency and its sidebands to give the modulation (or data signal) on V_1 a phase lead relative to V_4.

The former technique has been called[2] Type 1 compensation and the latter Type 2. Type 1 compensation is illustrated in Figure 2 and Type 2 in Figure 3; note that primed symbols represent the data signal which appears as modulation on the a-c signal represented by the corresponding unprimed symbol.

In the following discussion frequencies which are involved in the information carried by the data-transmission system will be referred to as data frequencies; those frequencies involved in the modulated a-c signal which carries this information will be called signal frequencies. For a Type 1 network the ratio V_1/V_4 will be defined as the signal transfer function and V_1'/V_4' as the data transfer function.

Since Type 2 compensation may be obtained with considerably less equipment than Type 1, it offers a decided advantage as far as weight, space, and maintenance are concerned. Type 2 compensation, however, possesses the following disadvantages:

1. There is a lower limit upon the data frequency at which useful phase lead may be obtained.
2. The compensation afforded by Type 2 networks varies with changes in the a-c carrier frequency.

The stated advantages of Type 2 compensation make this scheme extremely attractive if the attendant disadvantages may be overcome or tolerated. The first-mentioned disadvantage appears to be a basic one which restricts the use of Type 2 compensation to relatively "high-performance" servomechanisms. The purpose of this paper is to relax limitations resulting from the second-mentioned disadvantage by introducing techniques for minimizing the sensitivity of Type 2 networks to changes in carrier frequency.

Basic Action of Type 2 Lead Networks

Consider now the requirements on a network which is to impart phase lead to the modulation (or data signal) on a suppressed carrier modulated signal. If the network input voltage, V_4, consists of such a signal, as given in equation 1, the introduction of pure data phase lead will yield an output voltage, V_1, as given in equation 3.

$$V_4 = E \cos \omega_d t \cos \omega_c t, \tag{1}$$

$$= \frac{E}{2}\{\cos[(\omega_c+\omega_d)t] + \cos[(\omega_c-\omega_d)t]\} \tag{2}$$

$$V_1 = E \cos(\omega_d t + \theta_d) \cos \omega_c t \tag{3}$$

$$= \frac{E}{2}\{\cos[(\omega_c+\omega_d)t+\theta_d] + \cos[(\omega_c-\omega_d)t-\theta_d]\} \tag{4}$$

where

This paper is an abstract of a thesis submitted in partial fulfillment of the requirements for the Degree of Master of Science in Electrical Engineering.

The author appreciates the aid given by Dr. G. S. Brown, Director of the Servomechanisms Laboratory, Massachusetts Institute of Technology, and acknowledges the co-operation of many colleagues at the Laboratory, in particular, Mr. Paul Travers. Acknowledgment is due to the United States Air Forces, Air Materiel Command, Armament Laboratory, Wright Field, who sponsored the project under which this work was done.

Figure 2. Type 1 compensation

V_s = network input voltage
V_1 = network output voltage
ω_d = data frequency
ω_c = carrier frequency
θ_d = angle of data phase lead

Examination of equations 2 and 4 reveals that the network must impart a phase lead to the upper sideband of the carrier frequency and a phase lag to the lower sideband.

Type 2 Compensation Independent of Carrier Frequency

A more exact approach to the problem of design of Type 2 networks may be made if one seeks the relations between the signal transfer function and the data transfer function of a network which operates upon a modulated signal. It is desirable to construct the network signal transfer function so that no quadrature carrier components appear at the output of the network since most a-c output members are sensitive only to carrier components which are in phase with a fixed phase reference, ψ_R and are apt to be adversely affected by quadrature carrier-components. It has been shown* that the following constitutes a sufficient (although not necessary) set of conditions which guarantee that a network with signal transfer function $H(j\omega)$ will have a data transfer function $G(j\omega_d)$ and that no quadrature carrier components will be produced.

$$|H_e(\omega_d)| = |G(j\omega_d)| \tag{5}$$

$$\phi_0(\omega_d) = \angle G(j\omega_d) \tag{6}$$

$$|H_o(\omega_d)| = 0 \tag{7}$$

$$\phi_e(\omega_d) = \psi_R - \psi_c \tag{8}$$

where

ω = signal frequency
ω_d = data frequency
ω_c = carrier frequency
ψ_R = carrier reference phase angle
ψ_c = phase angle of carrier at network input

and the even component of $|H(j\omega)|$ taken about ω_c

$$|H_e(\omega_d)| = 1/2\{|H[j(\omega_c+\omega_d)]| + |H[j(\omega_c-\omega_d)]|\}$$

and the odd component of $|H(j\omega)|$ taken about ω_c

$$|H_o(\omega_d)| = 1/2\{|H[j(\omega_c+\omega_d)]| - |H[j(\omega_c-\omega_d)]|\}$$

* The development of these conditions, first carried out by Professor G. C. Newton of the Massachusetts Institute of Technology may be found in reference 3.

The even component of $\angle H(j\omega)$ taken about ω_c

$$\phi_e(\omega_d) = 1/2\{\angle H[j(\omega_c+\omega_d)] + \angle H[j(\omega_c-\omega_d)]\}$$

The odd component of $\angle H(j\omega)$ taken about ω_c

$$\phi_o(\omega_d) = 1/2\{\angle H[j(\omega_c+\omega_d)] - \angle H[(j\omega_c-\omega_d)]$$

These conditions require that $H(j\omega)$ have magnitude symmetry and phase assymetry about ω_c.

If the network data transfer function, $G(j\omega_d)$, is to be independent of ω_c, it may be seen from equations 5 through 8 that the following constitutes a set of sufficient conditions to be imposed on the signal transfer function, $H(j\omega)$

$|H_e(\omega_d)|$ must be invariant with ω_c (9)

$\phi_0(\omega_d)$ must be invariant with ω_c (10)

$|H_o(\omega_d)| = 0$ for all ω_c (11)

$\phi_e(\omega_d) = \psi_R - \psi_c$ for all ω_c (12)

A signal transfer function which is sufficient (although not necessary) to satisfy equations 9, 10, and 11, and which will introduce data phase lead, is offered by the $H(j\omega)$ illustrated in Figure 4. To satisfy equation 12, it will be necessary to introduce a second network to vary the phase of the carrier at the input terminals of the first network. If $H_c(j\omega)$ is defined such that

$$\psi_c = \angle H_c(j\omega) \tag{13}$$

the transfer function $H_c(j\omega)$ illustrated in Figure 5 will satisfy equation 12 provided the network which possesses this transfer function is placed at such a position in the system that it operates on the unmodulated carrier so as to vary ψ_c.

Reference to equations 1 through 4 reveals that the data transfer function associated with these "ideal" characteristics has a linearly increasing phase lead characteristic and a constant amplitude characteristic. Such a function, although different from conventional lead network data transfer functions, may be used to good advantage in many applications.

The "ideal" characteristics of Figures 4 and 5 violate the laws of minimum phase networks; hence, they may be approximated only over a small range of frequencies. The frequency range over which a valid approximation may be made is a function of the order of the transfer functions used to approximate $H(j\omega)$ and $H_c(j\omega)$.

Approximation of Ideal $H(j\omega)$

A preliminary investigation revealed that approximation of the ideal $H(j\omega)$ by means of a transfer function involving quadratic factors yielded, in most practical cases, networks which were insensitive of ω_c over a frequency range which was too narrow for most practical applications. Thus it was decided that a transfer function of fourth order (two quadratic factors) was the least complex one which would give a good approximation to the ideal characteristics over a sufficiently wide frequency range. It also was found that the large rate of change of phase of $H(j\omega)$ which is necessary to obtain useful phase lead for data frequencies involved in most practical cases could be obtained only by employing underdamped quadratic factors in the numerator of $H(j\omega)$.

A transfer function which meets the above-stated requirements, and which may be used to approximate the ideal $H(j\omega)$ over a reasonable frequency range, is as follows

$$H(ju) = \frac{[1-(u^2/m^2)+j2\zeta_m u/m]\,[1-m^2u^2+j2\zeta_m mu]}{[1-(u^2/r^2)+j2\zeta_d u/r]\,[1-r^2u^2+j2\zeta_d ru]} \tag{14}$$

where

$u = \omega/\omega_c$ = nondimensional frequency ratio
ζ_m, ζ_d = damping coefficients
m, r = coefficients which determine the undamped natural frequencies of the quadratic terms

This function will have amplitude and phase characteristics of the form illustrated in Figure 6.

Study of this function revealed that the best approximation to the ideal characteristics of Figure 4 may be obtained by constructing $H(ju)$ to have linear phase shift over as large a frequency range as possible. This approach is possible because the amplitude characteristic associated with the phase characteristic just described will, in all cases, vary only a few decibels for excursions of the carrier frequency which give a large change (over 90 degrees) in the phase characteristics.

Define

Figure 3. Type 2 compensation

Figure 4 (left). Form of ideal $H(j\omega)$

Figure 6 (right). Form of fourth order $H(ju)$

$\phi = /H(j\omega)$

$a = \omega_d/\omega_c$ = nondimensional data frequency ratio

$\Delta\phi/\Delta a$, the slope of the network phase characteristic for frequencies near $u=1$, is a basic quantity since it determines the amount of phase lead which will be introduced at any data frequency. This quantity must be chosen so that the compensation afforded will best meet the requirements of the particular system under consideration.

For a network whose transfer function is as given in equation 14, optimum insensitivity to ω_c may be attained by choosing ζ_n, ζ_d, m, and r to give the maximum range of linear phase shift for a specified phase slope. The choice of these coefficients must, however, be tempered by the fact that noise considerations make it desirable to have network attenuation at $\omega = \omega_c$ a minimum. These two specifications are in conflict, and a compromise must be made. It was decided that transmission at $\omega = \omega_c$ of 20 decibels below network transmission at low and high frequencies is a value which is acceptable for many applications.

Graphical constructions which utilize plots of phase slope versus frequency for the function $1-u^2+j^2\zeta u$ have been used[3] to determine the relations between ζ_n, ζ_d, m, and r which yield the maximum range of linear phase shift along with network attenuation of approximately 20 decibels for a specified phase slope, $\Delta\phi/\Delta a$. These relations are contained in Figure 7 along with the stipulation that

$$\zeta_d = \zeta_n \tag{15}$$

For specified phase slope, $\Delta\phi/\Delta a$, an $H(ju)$ constructed with the coefficients obtained from these relations will have linear phase shift for u between $1/m$ and m. Thus Figure 7 reveals that the extent of the range of linear phase shift varies inversely as phase slope, and the tolerance on ω_c must be made more strict for large values of phase slope than for small ones.

Approximation of Ideal $H_c(j\omega)$

The form of $H_c(j\omega)$ is dependent upon the value of ψ_R called for by a specific application. As an example $\psi_R = -90$ degrees will be considered. This value is applicable to the case of a 2-phase a-c motor servomechanism. In general, a second-order transfer function may be used to approximately $H_c(j\omega)$ since:

1. Failure to meet exactly equation 12 results in second-order effects.

2. The phase characteristic of $H_c(j\omega)$ must be linear only over the frequency range covered by a varying carrier frequency, while that of $H(j\omega)$ must be linear over the range covered by the varying carrier frequency and its sidebands.

A function which will satisfy equation 12 over a limited frequency range is

$$H_c(ju) = \frac{1}{1-u^2+j2\zeta_c u} \tag{16}$$

If $H(ju)$ is constructed with the coefficients of Figure 7, the phase slope of $H_c(ju)$ will be the negative of that of $H(ju)$ for u between $1/m$ and m providing

$$\zeta_c = \frac{m^2-1}{2m}\cot^{-1}\left[\left(\frac{m^2-1}{2m}\right)\frac{\Delta\phi}{\Delta a}\right] \tag{17}$$

is used in equation 16.

Choice of Phase Slope

For a specified phase slope of $H(ju)$, $\Delta\phi/\Delta a$, the restriction to fourth-order $H(ju)$ with optimum linear phase shift characteristic fixes $H(ju)$ and hence $G(ja)$, the data transfer function. It remains to integrate the choice of $\Delta\phi/\Delta a$ with the requirements of the particular servomechanism under consideration. Figures 8(A) and 8(B) show the amplitude and phase characteristics of the data transfer functions which result from networks constructed to give the fourth-order $H(ju)$ of equation 14 with coefficients obtained from Figure 7. Curves are shown for several values of $\Delta\phi/\Delta a$.

Define

Figure 5 (left). Form of ideal $H_c(j\omega)$

Figure 7 (right). ζ_n, m, and r versus $\Delta\phi/\Delta a$

Figure 8(A) (left). $|G(j\alpha)|$ versus α

Figure 8(B) (right). $G(j\alpha)$ versus α

$\mathfrak{A}$ = system input

$\mathfrak{C}$ = system output, the controlled variable

M_p = peak value of $\left|\dfrac{\mathfrak{A}(j\omega_d)}{\mathfrak{C}(j\omega_d)}\right|$

ω_{dr} = value of ω_d at which M_p occurs

If the amplitude-phase plot of the uncompensated transfer function of the servomechanisms under consideration is available, the designer may use the characteristics of $G(j\alpha)$ in the usual trial-and-error synthesis to determine the values of $\Delta\phi/\Delta\alpha$ and loop gain which give the desired M_p and ω_{dr}.

A less precise, but very rapid, method of determining $\Delta\phi/\Delta\alpha$ may be used if one is satisfied to specify that $G(j\alpha)$ shall introduce a specified data phase shift, θ_{ds}, at one specified data frequency, ω_{ds}. On the assumption that phase of $G(j\alpha)$ increases linearly with "α" (a valid approximation since $H(ju)$ was designed to have a linear phase characteristic)

$$\frac{\Delta\phi}{\Delta\alpha} = \theta_{ds}\frac{\omega_c}{\omega_{ds}} \tag{18}$$

The allowable tolerance on ω_c is related to the extent of the region of linear phase shift of $H(j\omega)$. Since this quantity is fixed once $\Delta\phi/\Delta\alpha$ is chosen, carrier frequency tolerance is related to $\Delta\phi/\Delta\alpha$. Note that the problem of maintaining the network data transfer function, $G(j\alpha)$, invariant with ω_c is not merely one of restricting ω_c to the region of linear phase shift of $H(j\omega)$; the band of frequencies represented by ω_c plus and minus the highest significant data frequency must be restricted to this region. The problem is further complicated by the fact that in most cases reasonable variations in the data transfer function are allowable. Hence the allowable tolerance on ω_c is a function of $\Delta\phi/\Delta\alpha$, the bandwidth of significant data frequencies, and the allowable variation in $G(j\alpha)$.

Assume that the highest data frequency of interest is the system resonant frequency, ω_{dr}, and that the shift in $G(j\alpha)$ may be represented by $\Delta\theta_{dr}$, the change in $\underline{/G(j\alpha)}$ at $\omega_d = \omega_{dr}$.

Define

n = allowable fractional deviation of ω_c from normal

$b = n + \dfrac{\omega_{dr}}{\omega_c}$

$\Delta\theta_{dr,\max}$ = maximum allowable change in $\underline{/G(j\alpha)}$ at $\omega_d = \omega_{dr}$

A graphical construction based on the deviation of $\underline{/H(ju)}$ from linearity results in the curves of Figure 9, which give b as a function of $\Delta\phi/\Delta\alpha$ for several values of $\Delta\theta_{dr|\max}$. Thus once $\Delta\phi/\Delta\alpha$ has been established, it is only necessary to estimate $\Delta\theta_{dr|\max}$ refer to Figure 9, and utilize the relation

$$n = b - \frac{\omega_{dr}}{\omega_c} \tag{19}$$

to compute the tolerance which must be placed on ω_c.

It should be pointed out that it is possible to follow this procedure in reverse; that is, for a given specification of carrier frequency tolerance, it is possible to determine the maximum value of $\Delta\phi/\Delta\alpha$ which may be used.

It has been shown in the foregoing discussion that for Type 2 networks restricted to fourth-order transfer functions with maximum range of linear phase shift, fixing the values of $\Delta\phi/\Delta\alpha$ and loop gain fixes ω_{dr}, M_p, and n for any given system. Hence one may specify only two of the variables ω_{dr}, M_p, and n since in so doing he fixes the third.

Network Realization

$H(ju)$ has been realized as two networks separated by a buffer amplifier, rather than as a single network. The reasons for this decision are as follows:

1. The design procedure is simplified.
2. Such a configuration allows one to tune the networks for proper operation, thus eliminating the necessity for maintenance of strict element tolerances.

$H(ju)$ may be realized with the network of Figure 10. Detailed design equations and adjustment procedures for this network are presented in Appendix II. The network which produces $H(ju)$ will henceforth be referred to as the main compensating network.

For the case of $\psi_R = -90$ degrees, $H_c(ju)$ may be realized with the network of Figure 11. Design equations and adjustment procedures for this network are presented in Appendix II. The network which yields $H_c(ju)$ will henceforth be referred to as the carrier reference network.

It is of interest to note the practicability of building these networks with physical inductors. For a coil which may be represented as a resistance, R, in series with a pure inductance, L, define

$$Q = \frac{\omega_c L}{R}$$

It has been demonstrated[3] that the highest value of Q required (for the

Figure 9 (left). $\Delta\phi/\Delta a$ versus b

Figure 10 (above). Network for realization of $H(ju)$

greatest $\Delta\phi/\Delta a$ which falls on Figure 7) is approximately 50. Since such a value may be attained at frequencies near 60 or 400 cycles per second (the most commonly encountered values of ω_c), there should be no difficulty in building any networks called for.

System Noise

In general one may expect trouble from the usual sources of data frequency noise (such as backlash in gears, and variations in amplifier d-c supply voltages) as well as from harmonic components of the carrier frequency which are either present in the a-c supply or generated within the system.

As for all lead networks, data noise frequencies which lie in the high-frequency range are accentuated by the compensating network. α_d, the ratio of $|G(ja)|$ at very high frequencies to $|G(ja)|$ at very low frequencies, may be taken as a measure of this effect. This quantity is tabulated for several values of $\Delta\phi/\Delta a$ in Table I. This tabulation indicates that difficulties caused by data frequency noise sources will be of the same degree as those encountered in many systems using d-c lead compensation since $\alpha_d = 20$ decibels is a figure which is frequently used in the design of d-c lead networks.

The presence of harmonic components of ω_c in the carrier signal is undesirable for the following two reasons:

1. Such components result in heating of the output member.

2. If present is sufficient magnitude, harmonics may cause saturation of one or more components of the system.

A measure of the amplification given the kth harmonic of ω_c by the main compensating network is given by α_k, where

$$\alpha_k = \frac{|H(ju)|_{u=k}}{|H(ju)|_{u=1}} \tag{20}$$

and $k = 2, 3, 4, \ldots$.

Table I lists values of α_k for several values of $\Delta\phi/\Delta a$. (For k greater than 3, α_k may be taken as approximately equal to α_d.) Reference to this table will allow the designer to estimate the level below which the harmonic content of V_4, the error signal, must be held to avoid exceeding a prescribed harmonic content of V_1, the control signal.

Harmonics which are present in the a-c power source may be reduced to the required level by filtering at the supply terminals. Harmonics generated within the system present no such simple problem since attempts to reduce them by means of filters will, unless special care is taken, result in an alteration of $H(ju)$. It is best to hold such harmonics to the desired level by careful choice and design of system components.

Table I. α_d and α_k Versus $\Delta\phi/\Delta a$

$\Delta\phi/\Delta a$, Degrees	α_d Decibels	α_k, Decibels $k=1$	$k=2$
378	22.8	25.5	26.1

Experimental Studies

The system illustrated in Figure 12 was constructed to provide a basis for experimental verification of the theoretical results as well as to provide some insight into the practical problems involved in the use of the carrier compensation scheme presented in this paper.

Since the uncompensated error transfer function of this system is a second-order function, it is theoretically possible to design compensation to yield any specified system resonant frequency. The following basic specifications were assigned as being typical values which might be encountered in practice:

$\omega_{dr} = 20$ cycles per second
$M_p = 1.5$
$n = \pm 5$ per cent

The components used include the following:

1. Output member: Kearfott *R-103-1A* 2-phase motor, 400 cycles per second, fixed phase—115 volts, control phase—26 volts.

2. Data transmitters: two Bendix *AY-101D* autosyns.

Detailed design of the compensation networks is carried out in reference 3. It is therein shown that for this servo system design of compensation to yield $\omega_{dr} = 20$ cycles per second and $M_p = 1.5$ gives $n = \pm 8$ per cent (approximately); hence the specification on carrier-frequency tolerance will surely be met.

With a carrier frequency of 400 cycles per second it was desired that the loop gain be adjusted for $\omega_{dr} = 20$ cycles per second. The extreme complexity of the frequency-response measurement, however, made this adjustment a very difficult trial-and-error process. Hence, when a condition of $\omega_{dr} = 18$ cycles per second was reached, it was decided that this con-

Figure 12. Servo schematic diagram

dition was sufficiently close to the design specifications. Correspondence between theoretical and actual performance may be determined for this setting as readily as for $\omega_{dr} = 20$ cycles per second.

With loop gain thus set the system frequency-response characteristics were experimentally determined for carrier frequencies of 380, 400, and 420 cycles per second. The results are plotted in Figures 13 and 14. From these curves it may be seen that if carrier frequency is kept within the specified range of 400 cycles per second ± 5 per cent, the variation in ω_{dr} will not be greater than 2 cycles per second and M_p will not change by more than 1.4 decibels. By visual inspection of the servo response to various types of inputs it was determined that system performance was still acceptable when the carrier frequency varied by ± 40 cycles per second. Instability did not occur until the carrier frequency was varied 50 cycles per second from its normal value.

For $\omega_{dr} = 18$ cycles per second the following values were predicted by theoretical considerations:

$M_p = 4.3$ decibels
$K_v = 1{,}800 \text{ sec}^{-1}$

K_v is the velocity constant and is defined as the output speed per unit error. For a carrier frequency of 400 cycles per second and loop gain set to give $\omega_{dr} = 18$ cycles per second, the following values were measured experimentally:

$M_p = 3.8$ decibels
$K_v = 1{,}020 \text{ sec}^{-1}$

Thus the measured value of M_p checks within 0.5 decibel of the theoretical value, and the measured velocity constant is within 5 decibels of the analytically obtained value. Thus it may be said that the experimental results satisfactorily corroborate the theory.

Design Procedure

The following summary of network design procedure may help the reader to obtain a clearer picture of the relations between the three basic quantities, M_p, ω_{dr}, and n which are imposed by the networks introduced in this paper.

It is assumed that the designer starts with an amplitude-phase diagram of the uncompensated loop error transfer function.

1. Specify M_p, ω_{dr}, and n.
2. Utilize the curves of Figure 8 in a trial-and-error graphical process to determine the values of $\Delta\phi/\Delta a$ and loop gain which will give the required M_p and ω_{dr}. (If considered sufficiently accurate, equation 18 may be used to accomplish this step.)
3. Estimate the allowable change in phase shift introduced by the compensation at $\omega_d = \omega_{dr}$, and use Figure 9 to determine the value of b.
4. Compute $n = b - \omega_{dr}/\omega_c$.
5. If the specification on n is not met, the designer must decide whether he desires to relax the specifications on M_p and ω_{dr} so as to obtain the required n. If such is the case, ω_{dr} and/or M_p must be changed and steps 2 through 4 repeated until a satisfactory value of n is obtained.

Alternate procedure to be used if a specified tolerance on ω_c is to be obtained at all costs:

1. Specify n and ω_{dr}.
2. Compute $b = n + \omega_{dr}/\omega_c$.
3. Use Figure 9 to determine $\Delta\phi/\Delta a$.
4. Use Figure 8 to determine M_p and loop gain.
5. If the value of M_p thus obtained is not tolerable, ω_{dr} must be changed, and steps 2 through 4 repeated until a satisfactory value is obtained.

Once the value of $\Delta\phi/\Delta a$ has been established proceed as follows:

6. Pick m, r, and ζ_n from the curves of Figure 7.
7. Use equations 1A through 10A of

Figure 13 (left.) Sinusoidal steady-state response $|C/R|$ versus frequency

Figure 14 (right) Sinusoidal steady-state response $\angle C/R$ versus frequency

Appendix II to design the main compensation network.

8. If $\psi_R = -90$ degrees is to be used (as in the case of a 2-phase a-c motor servomechanism), equations 11A through 13A of Appendix II may be used to design the carrier reference network.

9. If ψ_R is to be other than -90 degrees, the carrier reference network must be designed to satisfy equation 12.

Conclusions

1. Ideal network characteristics which yield carrier compensation completely independent of carrier frequency have been developed. Since, however, the specified amplitude and phase characteristics violate the laws of minimum phase networks, these ideal characteristics may be approximated only over a finite range of frequencies.

2. Techniques for obtaining the best fourth-order approximation to these characteristics have been presented.

3. Network design has been integrated with servomechanism requirements; in this process carrier-frequency tolerance has been placed on a quantitative basis.

4. Practical difficulties imposed by nonideal inductors and system noise have been considered. In no case covered by the design curves presented will these effects impose insurmountable limitations.

5. Experimental studies have corroborated the theoretical prediction that it is practical to employ the networks discussed in this paper to meet the requirements of many a-c systems, which, because of frequency instability in the a-c supply, would not receive adequate compensation from previously developed carrier compensation schemes.

α_d = attentuation ratio of main network
α_k = amplification of kth harmonic in main network
ζ_c = nondimensional damping ratio of $H_e(j\omega)$
ζ_d, ζ_n = nondimensional damping ratios in $H(j\omega)$
θ_d = data phase lead angle
θ_{dt} = angle of $G(j\omega)$ at ω_{dt}
$\phi_e(\omega_d)$ = even component of $\angle H(j\omega)$
$\phi_o(\omega_d)$ = odd component of $\angle H(j\omega)$
ψ_c = phase angle of carrier at input to main network
ψ_R = carrier reference phase angle
ω_c = carrier frequency (a constant)
ω_d = data frequency (a variable)
ω_{dr} = data frequency corresponding to M_p
ω_{dt} = specific data frequency

Appendix II

Network Design Equations

Define Z_i = network input impedance for $\omega = \omega_c$. For the main compensation network

$$L_{2a} = \frac{|Z_{1a}|}{m^2\omega_c\sqrt{(2\zeta_n r)^2+(r^2-1)^2}} \tag{1A}$$

Table II. Network Adjustment Procedure

Adjust the Series Combination	For Resonance at the Frequency
1 ..... L_{2a}, C_{3a}	$m\omega_c$
2 ..... L_{2a}, L_{1a}, C_{1a}	ω_c/r
3 ..... L_{2b}, C_{3b}	ω_c/m
4 ..... L_{2b}, C_{3b}, C_{1b}	$r\omega_c$
5 ..... L_e, C_e	ω_c

$$L_{1a} = L_{2a}(m^2r^2-1) \tag{2A}$$

$$C_{3a} = \frac{1}{m^2\omega_c^2 L_{2a}} \tag{3A}$$

$$R_{2a} = 2\zeta_n m\omega_c L_{2a} \tag{4A}$$

$$R_{1a} = R_{2a}(mr-1) \tag{5A}$$

and

$$L_{2b} = \frac{|Z_{1b}|}{\omega_c\sqrt{(2\zeta_n r)^2+(r^2-1)^2}} \tag{6A}$$

$$C_{3b} = \frac{m^2}{\omega_c^2 L_{2b}} \tag{7A}$$

$$C_{1b} = \frac{C_{2b}}{(m^2r^2-1)} \tag{8A}$$

$$R_{2b} = \frac{2\zeta_n\omega_c L_{2b}}{m} \tag{9A}$$

$$R_{1b} = R_{2b}(mr-1) \tag{10A}$$

Construction of the network of Figure 10 as called for by these equations yields a transfer function equal to $1/m^2r^2$ times the $H(j\omega)$ of equation 14.

For the carrier reference network with $\psi_R = -90$ degrees

$$R_c = Z_{1c} \tag{11A}$$

$$L_c = \frac{R_c}{2\zeta_c\omega_c} \tag{12A}$$

$$C_c = \frac{1}{\omega_c^2 L_c} \tag{13A}$$

Network Adjustment

The adjustments shown in Table II, carried out in the order given, will yield proper network operation. Resonance is defined as the condition for which current and voltage are in phase.

Discussion

George M. Attura (Industrial Control Company, Bronx, N. Y.): The problem of carrier frequency shifts in a-c servos has been under consideration by our group. It has been extremely interesting to hear of Mr. Notthoff's work, since our own efforts at analysis have led us to an approach somewhat different from that discussed in his paper.

It can be said that the basic theme of Mr. Notthoff's work is to eliminate by network design the envelope distortion which arises from the departure from conjugate transmission for the two sidebands when the carrier frequency shifts away from the resonant frequency of the notch network used for stabilization. To understand this it is necessary to understand the derivation of the conditions referred to as sufficient to assure that no quadrature components will be produced at the output of a network (equations 5, 6, 7, and 8).

It can be shown[1] that if a suppressed carrier sinusoidal modulation (V_e, equation 1) is impressed upon some network with signal transfer function $H(j\omega)$, the output signal can be resolved into two distinct sinusoidal suppressed carrier envelopes, whose carrier and modulation phases are in exact quadrature one with the other, for example

$$V_1 = E\frac{A_l+A_u}{2}\cos(\omega_d t+\phi_d)$$

$$\cos(\omega_c t+\phi_c)(\text{signal envelope})$$

$$+E\frac{A_l-A_u}{2}\sin(\omega_c t+\phi_c)$$

$$\sin(\omega_c t+\phi_c)\text{(quadrature envelope)}$$

where

$\omega_u=\omega_c+\omega_d$ = upper sideband frequency
$\omega_l=\omega_c-\omega_d$ = lower sideband frequency
A_u = network transmission at upper sideband
A_l = network transmission at lower sideband
ϕ_u = phase angle of upper sideband
ϕ_l = phase angle of lower sideband

and the rest of the symbols are the same as those used in the paper under discussion.

Now it is assumed that the presence of the quadrature envelope causes the reduction in damping observed experimentally in carrier frequency servos with unregulated carriers. Mr. Notthoff suggests that the $H(j\omega)$ be so shaped that its amplitude transmission is invariant about the carrier frequency. This suppresses the carrier of the quadrature envelope, for its amplitude is the difference between the transmissions of $H(j\omega)$ at the lower and upper sidebands. This seems to be accomplished by two cascaded resonant networks, tuned to different frequencies, whose over-all transmission is that of Figure 6.

Thus equation 11 gives a condition which makes it necessary that the amplitude of the quadrature envelope be zero throughout the range of carrier frequencies encountered. The type of stabilization which this type of network gives is pure phase lead, without the attendant rise in the amplitude transmission for the sidebands that is characteristic of the more commonly used quasi-derivative networks (parallel-T, bridged-T, and so forth).

While the results of this approach are certainly interesting and valid, it is questionable whether the best engineering compromise results in forcing the burden of quadrature envelope suppression on the stabilizing network itself. In our own work we have seen carrier frequency servos, stabilized by a conventional parallel-T, exhibit good stability margins over carrier frequency shifts greater than 50 cycles away from the center frequency of 400 cycles.

This observation suggested a study into the basic effects of the amplitude and phase asymmetry resulting from either the network configuration itself, or an otherwise symmetrical $H(j\omega)$ with a carrier frequency shifted from its resonant point.

In an unpublished thesis entitled Envelope Transfer Functions in Carrier Frequency Servomechanisms which I wrote, it was shown that the burden of quadrature envelope suppression could often be assumed by the load actuator itself.

These carrier frequency actuators, whether they be 2-phase induction motors, a-c torque motors, or phase-sensitive detectors, all have the characteristic of suppressing entirely any carrier frequency signal whose phase is in quadrature to some preferred phase ψ_R. Thus if the carrier phase of the signal envelope of equation 1 of the discussion is adjusted to be in phase with ψ_R, the carrier phase of the quadrature envelope will always be in quadrature to ψ_R, and no component due to this quadrature envelope will be present in the output of the actuator. It should be noted that a considerable simplification results since the networks necessary to generate $H_c(j\omega)$ are not required, and the damping circuits themselves are the relatively simple parallel-T, bridged-T, and so forth.

The analysis by which this may be proved rigorously is too detailed and lengthy to allow presentation here. It is hoped that the opportunity shall arise in the near future for publication of all the material. The major conclusions can be given here:

1. A carrier frequency shift will not destroy the damping introduced by a notch network provided the sidebands still fall on a portion of the $H(j\omega)$ which closely approximates that of an ideal derivative device.

2. Assuming a damping network configuration chosen to introduce the maximum data phase lead in the vicinity of the load's corner frequency, then no reduction in the stability margins of the servo-loop will be observed for carrier shifts smaller than the load corner frequency.

It can be seen that the higher the performance of the servo with centered carrier frequency, the greater the allowable carrier frequency shift. Or putting it another way, insensitivity to the carrier frequency shifts encountered in inverters for airborne equipment can be achieved by choosing servo loops that have extended frequency response.

Where the load time constant is great, then the allowable carrier frequency shift is too small to be of practical use. Here the method of Mr. Notthoff should find fruitful application since it is theoretically applicable to any servo regardless of load time constant. There does seem to be a limitation on this, and Mr. Notthoff himself mentions it when he states that there is a "lower limit upon the data frequency at which useful phase lead may be obtained." This limitation is caused by the impracticality of designing networks which give very high, phase slopes about the center frequency and hence significant data frequency phase lead for small values of ω_d. These networks are impractical because of the great amount of carrier attenuation necessary, with its attendant harmonic and noise frequency accentuation, and the requirements of very high inductance Q's.

In conclusion, we can attempt to tabulate the different methods of carrier frequency stabilization, insofar as the carrier frequency shift problem is concerned.

1. Load tachometric feedback from 2-phase induction generators will function well regardless of load time constant over a very broad range of carrier frequency shifts.

2. Where the load time constant is quite large, aside from 1 above, Type I compensation must be employed.

3. Where the load time constant is such that the first corner frequency of the load is beyond the region of 2 above, but still lower than the carrier shift required, then the technique of Mr. Notthoff is applicable.

4. Where the first corner frequency of the load is greater than the carrier frequency shift required, then the techniques suggested by Mr. Notthoff, though applicable, are not required, and the conventional notch networks can be used, with the attendant simplification of the accessory equipment and circuitry.

1. STABILIZATION OF CARRIER FREQUENCY SERVOMECHANISMS—GAIN PHASE MARGIN DIAGRAMS OF CONTROLLER CHARACTERISTICS, A. SOBZYK. *Journal* (Franklin Institute, Philadelphia, Pa.), volume 246, July 1948, pages 21–43.

Arthur P. Notthoff, Jr.: Mr. Attura's discussion is, in general, quite applicable. His presentation of the possible applications for the networks presented in this paper as contrasted with more familiar compensating schemes should be of particular interest to the reader.

Mr. Attura suggests that the reduction in damping afforded by Type II networks which accompanies a carrier frequency shift is caused by the presence of a quadrature envelope at the output member. Such cannot be the case since, as he points out, virtually all a-c output members act so as to reject any quadrature signal. The reduction in damping (or data phase lead) results from the alteration in network data transfer function caused by carrier shifts. The networks presented in this paper were designed to give an invariant data transfer function over a wide range of carrier frequencies; the attendant suppression of quadrature components is of secondary interest.

It may be shown that a reduction in data phase lead must accompany a carrier shift for any single cascaded Type II network (such as a parallel-T). The importance of a given carrier shift is dependent upon the servo bandwidth and stability margin (a criterion of which is given by $M\phi$). The frequency shift which may be tolerated by a parallel-T network in any given application may certainly be placed on a rapidly ascertainable quantitative basis as has been done for the networks of this paper. The author eagerly looks forward to publication of such work.

Improvements in the Characteristics of A-C Lead Networks for Servomechanisms

DONALD McDONALD
MEMBER AIEE

ELECTRIC lead networks are used quite extensively to improve the response of servomechanisms.[1] Such lead networks may be required to operate on the servo error voltage, on the input or output signal voltages separately, on the feedback voltage from an output tachometer, on various internal loop voltages, and on other signals. In many cases, the input voltage to the lead network is a modulated suppressed-carrier voltage, and it is necessary that the output voltage of the lead network also be a modulated suppressed-carrier voltage of the same carrier frequency. Consequently, the basic d-c lead network of Figure 1(B), which is normally used where the output signal may be direct current, is not applicable by itself to these problems, and an a-c lead network must be used.

The conventional a-c lead networks do not operate on their input signals so effectively as does the network of Figure 1(B) in a d-c servomechanism. It is the purpose of this paper to suggest modifications in design and in the components used which will improve the characteristics of a-c lead networks.

Conventional A-C Lead Networks

Before considering improvements in the characteristics of a-c lead networks, it is desirable to summarize the general characteristics of these conventional a-c lead networks.

When the input and output voltages of a lead network must be modulated suppressed-carrier voltages, two general classes of a-c lead networks are normally used. In the first class, illustrated by Figure 1(A) the a-c signal is demodulated, then the demodulated signal is passed through a d-c lead network, like the one of Figure 1(B), and lastly, the carrier is modulated with the output voltage of the d-c lead network. This class of a-c lead networks will be called a class-I network.

As noted before, regardless of the type of lead network, it may be stated that the essential characteristic of an a-c lead network is that it produce a pronounced, positive phase shift of the modulating envelope over specific portions of the modulating frequency band. The analytical equations[2] 5, 6, and 7 show that the class-I lead network of Figure 1(A) and Figure 1(B) does have a pronounced positive phase shift ϕ which reaches a maximum value of ϕ_m at a signal frequency of w_m. Figure 11 is a plot of the phase shift and magnitude characteristics of this lead network.

The demodulator and modulator circuits of the first class of a-c lead networks produce noise or ripple. Filter circuits added to the demodulator and modulator tend to reduce the magnitude of this noise. Unfortunately, the reduction in noise by this method is accompanied by a time delay or an effective negative phase shift of the modulating envelope. Such a negative phase shift may be partially compensated for by an increase in the attenuation of the d-c lead network. This increase in the attentuation will result in an increase of the over-all noise-to-signal ratio. Hence, in the class-I a-c lead network, an engineering compromise must be reached between the amount of noise suppressed by filters in the demodulator and modulator, and the increase in noise-to-signal ratio resulting from the increase in attenuation required to offset the effect of the filters. These several factors cause this class-I network to produce a smaller maximum positive phase shift than the d-c lead network can produce by itself.

An example of the second class of a-c lead networks is shown in Figure 2(A), and this class will be referred to as class-II networks. The parallel-T network of Figure 3 is another simple a-c lead network of class II.[3] The networks of Figures 2(A), 2(B), and 3 are only a few of the several types of networks belonging to this class. Equations 10 through 12 and equations 20 through 23 of Figures 2 and 3, respectively, show that these networks modify the envelope of the modulated signal in approximately the same fashion as does the circuit of Figure 1.[4] (The equations of Figures 2 and 3 and similar equations of following figures are written in terms of the modulating envelope. This is justified only when the upper and lower side bands have symmetrical attenuation and asymmetrical phase characteristics with respect to w_c. These requirements are satisfactorily met for these networks over the range of modulating frequencies specified.)

The application of these class-II networks is restricted by the following two factors:

1. Most a-c lead networks of the second class are quite sensitive to changes in the carrier frequency because a change in carrier frequency can reduce the effective lead developed by these networks and can, in some cases, produce lag instead of lead. This effect is more noticeable at 400 cycles per

Paper 50-46, recommended by the AIEE Feedback-Control Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 5, 1948; made available for printing December 1, 1949.

Therkelsen, University of Michigan, Aeronautical Research Center, in the preparation of some of the data and graphs, as well as for his helpful criticism.

Figure 1(A). Basic class-I a-c lead network

If

$$e_i = e \sin w_m t \sin w_c t \tag{1}$$

then

$$e_i' = e \sin w_m t \tag{2}$$

$$e_o = e_o' \sin w_c t \tag{3}$$

Figure 1(B). Basic d-c lead network

$$r = \frac{R_1 + R_2}{R_2}$$

$$T = R_1 C$$

$$\phi = \angle \frac{e_o'}{e_i'}$$

If

$$e_i' = e \sin w_m t \tag{4}$$

$$\frac{e_o'}{e_i'} = \frac{1}{r} \frac{1 + jw_m T}{1 + jw_m \frac{T}{r}} \tag{5}$$

Where maximum phase shift

$$\phi_{2m} = \sin^{-1}\left[\frac{r-1}{r+1}\right] \tag{6}$$

and occurs at

$$w_{2m} = \frac{\sqrt{r}}{T} \tag{7}$$

$$\left.\frac{e_o'}{e_i'}\right]_{w_m = \infty} \Big/ \left.\frac{e_o'}{e_i'}\right]_{w_m = 0} = r = \text{attenuation} \tag{8}$$

second than at 60 cycles per second, because it is the absolute change in carrier frequency which affects the network and, in general, 60-cycles-per-second sources are better frequency-regulated on an absolute basis than 400-cycles-per-second sources.

2. The maximum value of the lead time constant T of the second class of a-c lead networks is limited and this limits the minimum value of w_{2m}, the frequency at which the maximum positive phase shift of the modulating envelope occurs. (For the network of Figure 2(A), the maximum value of $T = 2L/R_3$ and for the network of Figure 3, the maximum value of $T' = 1/w_c$.) In some cases when the minimum value of w_{2m} is too large, it is possible to increase the phase shift at lower frequencies by increasing the attenuation. Unfortunately this increase in attenuation may increase the noise-to-signal ratio of the lead network sufficiently to offset any improvement derived from an increase in positive phase shift at lower frequencies.

Figure 2(B)[5] shows a modified form of the basic class-II a-c lead network. As will be noted from equations 16, 17, and 18, when the maximum phase shift ϕ_{2m} is the same for both the circuits of Figures 2(A) and 2(B), the minimum value of w_{2m} is smaller for Figure 2(B) than for Figure 2(A) by a factor of c. Inasmuch as the minimum value of r' is 1, the maximum value of c under the condition of equation 16 is r.

Modifications of the Class-I A-C Lead Network

As was mentioned before, the demodulator and modulator filters of Figure 1 (A) produce time delays or effective negative phase shifts of the modulating envelope. Figure 4(A) shows a circuit where the demodulator and modulator filters are used to an advantage. The arrangement of the components of Figure 4(A) shall be referred to as a feedback-type modification of class I. To simplify the consideration of this circuit, the time delays or phase shifts created by the filters of the demodulator and modulator have been lumped in the single resistance-capacitance time-lag network of Figure 4(A). Thus the minimum value of the time constant of the resistance-capacitance network of Figure 4(A) will be determined by the filters in the demodulator and modulator, but if required, additional filtering or delays may be added to increase this equivalent time constant.

The analytical expressions 33, 34, and 35 of Figure 4(A) show that the characteristics of this system are the same as for the basic class-I network. The attenuation r may be adjusted by adjusting the gains of the amplifier, demodulator, or modulator. The lead time constant T may be made as large as desired but does have a minimum value determined by the equivalent time constant of the demodulator and modulator filters which produce an acceptable noise level.

Figure 4(B) shows another arrangement of the components of the basic class-I a-c lead network and will be referred to as a parallel-type modification of class-I a-c lead network. The assumptions made in representing the circuit of Figure 4(A) are carried over into the circuit of Figure 4(B).

The analytical expressions 44, 45, and 46 show that the response of this network is similar to that of Figure 4(A). The parallel type has the limitation that,

Figure 2(A). Basic class-II a-c lead network

If

$$e_i = e \sin w_m t \sin w_c t \tag{9}$$

then

$$\frac{e_o'}{e_i'} \cong \frac{1}{r} \frac{1 + jw_m T}{1 + jw_m \frac{T}{r}} \text{ for } w_m << w_c \tag{10}$$

The maximum phase lead (of the signal)

$$\phi_{2m} = \sin^{-1}\left[\frac{r-1}{r+1}\right] \tag{11}$$

and occurs at

$$w_{2m} = \frac{\sqrt{r}}{T} \tag{12}$$

In general a primed variable denotes the envelope of the variable (this statement applies also to Figures 2(B), 3, 4(A), 4(B), 5, 6, 7, and 8).

Figure 2(B). Modification of the basic class-II a-c lead network

$$r' = \frac{R_1' + R_3}{R_3} \qquad T = 2\frac{L}{R_3} \qquad w_c = \sqrt{\frac{1}{LC}}$$

$$b = \frac{R_3 + R_4}{R_4} \qquad c = \frac{b-1}{b-r'} \qquad \phi' = \angle \frac{e_o'}{e_i}$$

$$\frac{e_o'}{e_i'} \cong \frac{b-r'}{br'} \frac{1 + jw_m cT}{1 + jw_m \frac{T}{r'}} w_m << w_c \tag{13}$$

Where

$$\phi_{2m}' = \sin^{-1}\left[\frac{cr'-1}{cr'+1}\right] \tag{14}$$

$$w_{2m}' = \sqrt{\frac{r'}{c}} \frac{1}{T} \tag{15}$$

If

$$cr' = r \tag{16}$$

then

$$\phi_{2m}' = \phi_{2m} \tag{17}$$

$$w_{2m}' = \frac{\sqrt{r'}}{T} \frac{1}{c} = \frac{w_{2m}}{c} \tag{18}$$

where r, ϕ_{2m}, and w_{2m} refer to Figure 2(A)

Figure 3. Parallel-T class-II a-c lead network

$$R_1C_1=\frac{1}{w_c}$$

Then if

$$e_1=e\sin w_s t\sin w_c t \tag{19}$$

$$\frac{e_2'}{e_1'}\cong\frac{1}{r}\,\frac{1+jw_sr T'}{1+jw_sT'}\qquad w_s\ll w_c \tag{20}$$

$$\phi=\angle\frac{e_2'}{e_1'} \tag{21}$$

$$\phi_{zm}=\sin^{-1}\left[\frac{r-1}{r+1}\right] \tag{22}$$

$$w_{zm}=\frac{1}{\sqrt{rT'}} \tag{23}$$

as noted from equation 43, the minimum value of the lead time constant is equal to r times the minimum value of the equivalent time constant of the demodulator and modulator filters. Inasmuch as this value may be too large for some servomechanism applications, the parallel type may not always be so useful as the feedback type.

The effectiveness of the demodulator and modulator filters or the complexities of the demodulator and modulator plus filters may be such as to limit the degree of suppression of noise generated. Such a limitation will establish the noise-to-signal ratio and determine the applicability of these circuits.

By a change in the type of components as well as the arrangement used in the basic class-I network, a system can be evolved having demodulators and modulators with excellent noise-to-signal ratios. Such a system will be referred to as an electromechanical a-c lead network—class I.

Electromechanical A-C Lead Networks—Class I

Figure 5 is an example of such a modified class-I network.[6,7] In its most general form, this network is equally applicable for d-c and a-c operation, but in this paper only its a-c form is discussed. In this system the motor functions as a demodulator and the generator as a modulator. Both of these functions are approximate with the limitations that w_s and the motor-generator speed be small compared to the carrier frequency and synchronous speeds, respectively. The analytical expressions of 57, 58, and 59 of Figure 5 show that the characteristics of this system are the same as for the basic class-I a-c lead network.* By proper ad-

* In the derivation of the equations of Figure 5 and following figures, it has been assumed that the torque developed by the motor is directly proportional to the excitation voltage. Actually, with increasing signal frequency the torque is no longer directly proportional to the excitation voltage but lags behind it in phase and is reduced in amplitude. This effect produces the equivalent of additional phase lags in the feedback path which increase the phase lead of the over-all system at higher frequencies.

$$\frac{e_2'}{e_1'} \cong \frac{Jp^2 + fp + (K_2 - K_1K_2K_3)}{Jp^2 + fp + K_2} \tag{89}$$

Let

$$e_2 = e \sin w_2 t \sin w_0 t \tag{90}$$

$$w_n^2 = \frac{K_2}{J} \tag{91}$$

$$c = \frac{f}{2\sqrt{K_2 J}} \tag{92}$$

$$q^2 = \frac{K_2}{K_2 - K_1K_2K_3} \tag{93}$$

$$u = \frac{w_2}{w_n} \tag{94}$$

$$\frac{e_2'}{e_1'} \cong \frac{1}{q^2}\ \frac{1-(qu)^2 + j2(qc)(qu)}{1-u^2 + j2cu} \tag{95}$$

Figure 9 (left). Electromechanical components of the network of Figures 7 and 8

justment of K_1, K_2, and K_3, it is possible to establish any value of attenuation r. The lead time constant T can be made as large as desired by the addition of inertia to the common motor-generator shaft. Unfortunately the minimum value of T is $(J_2+J_3)/f_2$ and this value may be too high for some servo applications.

The arrangement of the components of the circuit of Figure 5 is such that this type of electromechanical network will be referred to as a feed-back type. Another arrangement of the components of Figure 5 is shown in Figure 6 and will be referred to as an electromechanical a-c lead network of the parallel type. This parallel type of electromechanical network has characteristics similar to those of the feed-back type except that its lead time constant T is greater by a factor equal to the attenuation r. Consequently, in many cases the parallel type is not so useful as the feed-back type of electromechanical a-c lead network. It is of interest to note that the amplifier K_1 can be omitted in the parallel type.

Figure 7 is a schematic of another electromechanical a-c lead network—class I. It is of the feed-back type but, as indicated by equation 83, does not have the phase and amplitude characteristics of the basic class-I a-c network. This network is a resonant lead controller of class I. Figures 12, 13, 14, 15, and 16 show the phase and amplitude characteristics of this electromechanical system.

Figure 8 shows the parallel-type counterpart of the electromechanical a-c lead network of Figure 7. Its characteristics are similar to those of the feed-back type.

Of the several types of electromechanical a-c lead networks discussed, that of Figure 7 appears to have the most desirable characteristics and also to be the simplest to manufacture. Figure 9 is a cut-away view of a pilot design of this electromechanical system. The main components of the system are (1) an induction torque motor, (2) a combination induction pickoff and electric spring, (3) an eddy-current damper, and (4) inertia weights. The induction torque motor and the combination induction pickoff and electric spring are made of simple, punched laminations and bobbin-wound coils and are called Microsyn elements.[8]

The induction torque motor is excited by a fixed a-c reference voltage and by the signal voltage. It develops a torque proportional to the signal voltage which is virtually independent of the angular displacement of its rotor. The coils of the combination induction pickoff and electric spring are arranged so that there is a separate circuit for both the pickoff and electric spring. The pickoff circuit is excited with a-c voltage, and the circuit

Figure 14 (right). Log modulus and phase angle versus dimensionless frequency of the network of Figure 7 for $h = 1.75$

Figure 15 (left). Log modulus and phase angle versus dimensionless frequency of the network of Figure 7 for $h=2.25$

Figure 16 (right). Log modulus and phase angle versus dimensionless frequency of the network of Figure 7 for $h=3.0$

of the electric spring is excited with d-c voltage. This combination then produces a signal voltage and a torque, both of which are proportional to the angular displacement of the rotor from neutral. By changing the d-c excitation of the electric spring circuit, the torque gradient of the electric spring may be adjusted.

The eddy-current damper is made up of an aluminum damping disc and a multipole Alnico permanent magnet with its poles parallel to the axis of rotation. This magnet is threaded axially into the housing; therefore, it is possible to adjust the spacing between the magnet and damping disc, thus changing the damping coefficient f.

The total moment of inertia of the system may be changed by adjusting the position of the inertia weights.

Thus as there are three continuously adjustable parameters—the spring constant, the damping, and the moment of inertia—it is possible to adjust the two variables w_n and c independently. The attenuation factor h^2 also can be adjusted independently by changing the pickoff sensitivity or the amplifier gain.

As planned in a typical design, w_n and c are to be continuously adjustable from 1 to 6 cycles per second and 0.5 to 1 respectively. Over these ranges of network parameters, the maximum power consumption of the torque motor should not exceed one-third of a watt.

Changes in carrier frequency which will not prevent proper operation of any electromechanical components in the complete servo loop (such as motors and indicators) will not appreciably affect the operation of the electromechanical a-c lead networks described. Figures 12, 13, 14, 15, and 16 show that w_{pm} occurs near w_n, and, as noted before, w_n and hence w_{pm} may be adjusted to cover the region of frequencies 1 to 6 cycles per second. Also, as the network of Figure 7 is a resonant lead network, the maximum value of phase shift ϕ_{pm} produced by it may be made larger than for a simple lead network having the same attenuation or noise-to-signal ratio.

An example of the application of the electromechanical lead network of Figure 7 is shown in Figure 10. Here a 2-phase induction servo is being stabilized by the use of this electromechanical a-c lead network. As will be noted, the amplifier driving the servo motor is also used to drive the torque motor of the lead network. This is possible because of the very low power consumption of the torque motor.

In closing, if the feed-back paths of Figures 4(A), 5, and 7 are connected regeneratively, instead of degeneratively, and the parallel paths of Figures 4(B), 6, and 8 are connected so as to add, instead of subtract, these systems will become lag or integral networks instead of lead networks.

In general, it may be stated that the modifications in the circuit arrangements and the change in the type of components of the basic class-I lead network produces an a-c lead network which has all of the advantages of the class-I lead network with its disadvantages kept to a minimum. The general approach used in modifying the basic class-I a-c lead network has been to place all of the elements with negative phase shifts in a parallel or feed-back branch where they will effectively produce a lead instead of a lag. Thus by this procedure, the inherent and unavoidable delays that occur in many networks, such as in demodulators and modulators, can be put to an advantage instead of being a handicap.

The characteristics of the class-II a-c lead networks have been described in this paper in order to contrast more effectively the two classes, but no attempt will be made in this article to describe methods of improving the characteristics of the class-II a-c lead networks.

An Electronic Simulator for Nonlinear Servomechanisms

CHARLES M. EDWARDS
NONMEMBER AIEE

E. CALVIN JOHNSON, JR.
STUDENT MEMBER AIEE

Synopsis: An electronic computer for the simulation of autopilot servomechanisms is being developed as a small-scale flexible analog computer capable of reproducing electrically the dynamic behavior of systems in which certain of the dependent variables or their derivatives may be limited in magnitude but which otherwise can be characterized by linear differential equations having constant coefficients. Specifically, the simulator is being designed to represent on a one-to-one time scale several types of closed-cycle systems or servomechanisms which are linear except for possible limitations of such quantities as motor torque, output velocity, and output displacement.

THE Dynamic Analysis and Control Laboratory at the Massachusetts Institute of Technology has been constructing a large-scale analog computer, capable of solving the general equations of motion of an aircraft, which will be used primarily in the development of aircraft control systems. The "servo simulator" described in this paper is included as a portion of the computer to represent on a one-to-one time scale the dynamic characteristics of the control-surface servos. These servos usually are designed to operate linearly as proportional devices. However, a servo occasionally will be required to operate at the extreme limits of its physical capacity, beyond its linear range.

Some of these servos exhibit marked nonlinear effects which easily may be the most significant factors in determining the motion of the aircraft which they control. Systems, otherwise perfectly satisfactory, may even become unstable in the presence of certain types of nonlinearities. It is evident, therefore, that if simulation of the flight of an aircraft controlled by such servos is to be accurate, the nonlinearities in these servos must be represented. Moreover, if provision is made to simulate nonlinear servos, investigations can be made as to the extent to which nonlinearities in the control-surface servos can be tolerated, still maintaining satisfactory control characteristics and, above all, absolute stability. Information of this nature would aid in effecting the best compromise between size of the servo and its region of linear operation.

The exact nature of the nonlinearities to be expected depends upon the particular servo employed. Certain types of nonlinearities are fairly common. For example, the control-surface deflection usually is limited either by external limit stops or by the limited stroke of the power-output device itself, as in a hydraulic ram. In the case of a clutch-powered servo, the control-surface velocity is limited to the velocity corresponding to the speed at which the clutch is driven. Other frequent causes of nonlinear behavior are amplifier overloading and magnetic saturation in electric motors. In general it is true that these systems behave in a manner essentially linear except that certain quantities such as motor torque, output velocity, and output displacement may be restricted, inherently or otherwise, to definite maximum values. To be sure, the systems may be subject to nonlinear damping and restoring forces as well; but such limitations as those on torque, velocity and displacement usually are responsible for the dominant nonlinear effects.

Although the servo simulator is intended primarily to serve as a link in the main Dynamic Analysis and Control Laboratory computer, it also is suitable for investigations of a more general nature pertaining to the design and performance of closed-cycle control systems. The simulator, in fact, is capable of representing any system of reasonable complexity in which certain of the dependent variables or their derivatives may be limited in magnitude, abruptly or gradually, but which system otherwise can be characterized by a set of linear differential equations with constant coefficients.

Derivation of the Analog of a Nonlinear Servomechanism

Any two systems, whether electrical, mechanical, hydraulic, or thermal, may be said to be analogous when there exists a definite parallelism in the form of the mathematical relations which represent them. Hence, for each quantity in a given system there may always be found a corresponding quantity in an analogous system which behaves identically. The first system, then, is represented or simulated by its analog. Electronic simulation of a system involves the identification of an analogous electronic element with each portion of the given system to be represented explicitly. Logically, then, the simulation of a specific system should begin with a careful analysis of the system in mathematical terms and proceed through the medium of mathematics

Y., January 30-February 3, 1950. Manuscript submitted November 3, 1949; made available for printing December 7, 1949.

Charles M. Edwards and E. Calvin Johnson, Jr. are both with the Dynamic Analysis and Control Laboratory, Massachusetts Institute of Technology, Cambridge, Mass.

The authors wish to express their gratitude to Dr. A. C. Hall for his active support in the development of this simulator and to thank F. C. McCoy for his assistance in construction of the equipment.

Figure 2 (left). Symbolic representation of the servomechanism of Figure 1

Figure 4 (right). Simplified analog of the servo of Figure 1

to the synthesis of a suitable analog.

As an illustration of the principles involved in such a synthesis, consider the simple servo shown schematically in Figure 1. The error quantity, θ_s, defined as the difference between the desired position, θ_i, and the actual position of the output shaft, θ_o, is converted to an appropriate signal which then drives the motor. The torque, τ_m, developed by the motor, assumed to be related to θ_s by the proportionality factor K_m, is utilized in accelerating the combined motor and load inertia, J_m, and in overcoming the equivalent viscous damping, B_m. The following equations describe the system mathematically

$$\theta_s = \theta_i - \theta_o \tag{1}$$

$$\tau_m = K_m \theta_s \tag{2}$$

and

$$J_m \frac{d^2\theta_o}{dt^2} + B_m \frac{d\theta_o}{dt} = \tau_m$$

or

$$J_m \frac{d^2\theta_o}{dt} + B_m \frac{d^2\theta_o}{dt} = \tau_m \tag{3}$$

These relations may be represented symbolically by the block diagram of Figure 2. If electronic elements are available which are capable of carrying out the operations of addition, constant multiplication or amplification, and integration as indicated in the diagram, the analog can be synthesized in exactly this form. For most purposes, however, this arrangement can be simplified considerably. For example, an amplifier and a series resistance-capacitance network may be substituted for the combination of adder, multipliers, and integrator which is required in Figure 2 to produce θ_o from τ_m. The analogy involved in this substitution is explained in Figure 3 by association of the differential equation which represents the amplifier and network

$$\frac{RC}{A}\frac{de_o}{dt} + \frac{1}{A}e_o = e_i \tag{4}$$

with equation 3, which relates, ν_m to $\frac{d^2\theta_o}{dt}$. The time constant, T_m, of the mechanical system is J_m/B_m, whereas in the electric circuit, T equals RC.

With the aid of this substitution and other minor simplifications, the electric analog shown in Figure 4 is obtained. Although the variable quantities are labeled exactly as they were in the original system, it should be understood that the diagram is meant to represent an electric system. This nomenclature has been adopted for the sake of simplicity and directness in emphasizing the relationships existing between the voltages in the analog and the quantities in the actual system.

Suppose, now, that it is desired to simulate the operation of such a system when there is added an external limit stop at the position θ_s. If the limit stop is to serve its purpose effectively, it must prevent the output, θ_o, from moving significantly beyond θ_s. Consequently, when the output strikes the limit, its velocity, and likewise the kinetic energy stored in the moving elements, must be reduced quickly to zero. In the electric analog of the simple servo, Figure 4, the output velocity is represented by the voltage across the network capacitor; the kinetic energy is represented by the energy stored in the capacitor, this energy being proportional to the square of the voltage across the capacitor. Evidently, then, when the output voltage attempts to rise beyond that voltage which represents the maximum allowable displacement, the voltage across the network capacitor must be reduced to zero. By this reasoning it is recognized that the method of simulation which limits the voltage at the output of the integrator does not provide a correct representation of the system. Because of the unilateral nature of electronic amplifiers and integrators, such a limiting could not affect the voltage across the capacitor. In fact, because of the increased error signal, the effect actually would be opposite to the one desired.

Consequently, it is necessary to examine the occurrence of displacement limiting from a more fundamental viewpoint.

As pictured in Figure 5, a stiffness, K_s, and a viscous damping, B_s, may be assigned to the stop. When θ_o is less than θ_s, the stop has no effect upon the behavior of the system. After the output strikes the limit stop, however, an additional torque, τ_s, is created which acts in opposition to the motor torque. Thus,

$$\tau_s = B_s \frac{d\phi}{dt} + K_s\phi \tag{5}$$

in which ϕ is defined as follows

$$\phi = \begin{cases} 0 & ; \theta_o < \theta_s \\ \theta_o - \theta_s & ; \theta_o \geq \theta_s \end{cases} \tag{6}$$

Equation 3, written for the system without limiting, now may be modified to include the effects of the limit stop

$$J_m \frac{d^2\theta_o}{dt^2} + B_m \frac{d\theta_o}{dt} = \tau_m - \tau_s \tag{7}$$

Figure 6 shows the symbolic representation of equations, 1, 2, and 7. The block labeled T.C. (so-called because of its electrical equivalent, the "threshold circuit") forms the quantity ϕ from θ_o and θ_s

Figure 3 (left). Analogous systems

Figure 5 (right). A simple servo with displacement limiting

Figure 6. Symbolic representation of the system of Figure 5

in accordance with equation 6.

If the electric analog were to be realized with the arrangement given in Figure 6, an ideal electronic differentiator would be required. Actually, duplication of equation 5 as it stands is found to be easier. Equation 5 may be written in terms of the differential operator p as

$$\frac{\tau_s}{\phi} = K_s(T_s p + 1) \equiv K_s G_s \qquad (8)$$

in which

$$T_s = \frac{B_s}{K_s}$$

The displacement-limiting unit to be discussed later contains both the threshold circuit and an electronic circuit with approximately the characteristic expressed in operational language by equation 8. The simplified electric analog, Figure 7, which makes use of this operational notation, now can be constructed.

The simulation of displacement limiting by the method just described, which is applicable to any system in which the required torque summation can be performed, involves two parameters of the limit stop, the stiffness and the damping. In most instances, these parameters are unknown. Usually it is known only that the limit stop functions in a positive manner to halt the output motion and that any additional effects which may be introduced by the dynamics of the limit stop are neither apparent nor significant in the normal operation of the system. Consequently, in simulating such systems it is necessary only so to adjust the displacement-limiting circuit that its effects, other than the desired positive limiting, are far removed in both magnitude and frequency from those caused by the principle characteristics of the servo. Figure 8 shows cathode-ray-tube displays of the output of a second-order servo, represented by Figure 7, when excited sinusoidally by a signal sufficiently large to cause limiting in both directions. In this particular case the undamped natural frequency of the system was 25 cycles per second, the nondimensional damping ratio 0.3, and the frequency of excitation 10 cycles per second. Correct adjustment of the displacement-limiting circuit is illustrated by Figure 8(A); Figures 8(B) and 8(C) respectively, show the results when the gain K_s is too low and when the time constant T_s is too small. The maladjustments in these latter two cases are greatly exaggerated; actually, the adjustments for good limiting are not critical.

Figure 8. Displacement limiting of a second-order system when excited sinusoidally

A. Correct limiting
B. Gain K_s too low
C. Time constant T_s too small

Figure 9. Autopilot simulator

Development of the electric analog in the manner just outlined has led to a system in which most of the variables of interest in the original servo, such as input, torque, velocity, and output, are represented by the voltage of some point with respect to a common terminal. Consequently, the analog is in general considerably more complicated than would be required to represent only the output-input relation of a system. Indeed, the behavior with respect to the input and output of the simple servo of Figure 1 can be simulated by a single-series resistance-inductance-capacitance network. The form of the analog shown in Figure 7, however, is convenient when it is necessary to study in detail quantities in the system other than the output. Moreover, the simulation of nonlinear effects often is greatly facilitated by the explicit appearance of the variables involved. For example, torque saturation and velocity limiting in the simple servo of Figure 1 can be represented by limiting the voltages in the analog which correspond to torque and velocity. In Figure 7 voltage limiters are shown at the appropriate places to accomplish this limiting. It should be emphasized that the voltage actually appearing across the network capacitor is the voltage proportional to the velocity. Hence it is this voltage which must be limited, not merely the voltage transmitted to the following elements. Consideration of the energy stored in the system makes this important difference obvious.

Description of the Simulator Components

Synthesis procedures such as those described lead to analogs which require, for representing the linear behavior of a system, the following electric computing elements: summing circuits, voltage amplifiers, integrators, and passive networks composed of resistance, capacitance and inductance. A study of several basic servos,[1] including those having types of power-output devices such as induction motors, d-c generators and motors, field-controlled d-c motors, magnetic clutches, hydraulic transmissions, and valve-controlled hydraulic motors indicates, moreover, that the most important nonlinearities in these systems can be represented with reasonable accuracy by the addition of voltage limiters and the special displacement limiting circuit. In view of the fact that a large number of components would be required to simulate control about three axes of an aircraft, it seemed advisable to arrange the computing components in such a fashion that the equipment could be used not only to simulate autopilot servos but also as a general mathematical tool to solve certain types of nonlinear differential equations. Consequently, a series of standard simulator units were built, incorporating the above-mentioned computing elements. Figure 9 shows a portion of the simulator which now is in use at the Dynamic Analysis and Control Laboratory. The final installation will consist of three racks of equipment containing the following units: 8 *RC* simple-lag networks; 2 *RLC* quadratic-lag networks; 9 integrator units; 12 limiter-amplifier units; 4 displacement-limiting units; 4 input units; and 4 output units. Summing circuits, coefficient potentiometers, and initial-conditions generators will be included also, together with the necessary power controls and means to zero set and calibrate the various units. Input and output terminals of all units will be available at a single patch board for flexible interconnection.

Figure 13. The threshold circuit

The simple-lag network, Figure 10, provides a continuously variable time constant ranging up to one second. The desired accuracy is obtained through the use of precision wire-wound resistors, a 10-turn micropot for fine control, and polystyrene capacitors accurate to within 1 per cent. Similar resistors and capacitors, together with a precision inductor, are used in the quadratic-lag network, the natural frequency and damping ratio of which may be varied in steps from 31.6 to 200 cycles per second and from 0.1 to 1.0, respectively.

Figure 11 shows the basic elements of the circuit employed in the integrator unit. The characteristic of integration is obtained by capacitive feedback around a high-gain direct-coupled amplifier. The amplifier in this unit is of a special form, similar to that developed by the Radio Corporation of America and others to provide stabilization against steady drifts.[2] It consists essentially of two amplifiers, Figure 11. One, denoted by α_2, provides "driftless" gain for steady and slowly changing signals by means of a mechanical modulator, a capacitively-coupled amplifier, and a synchronous demodulator. The other amplifier, consisting of the cathode-coupled stage and α_1, is a conventional direct-coupled am-

Figure 12. Servo-simulator limiter-amplifier unit

Figure 13 (left). Action of the auxiliary switching circuit

Figure 16 (right). Transient response of a second-order system to a step input

plifier. The two sections are so combined that drifts in the cathode-coupled stage and in α_1 are reduced in their effect on the output by the factor α_2.

If the feed-back capacitor in Figure 11 is replaced by a resistor, the circuit becomes a sign-changing voltage amplifier. In the integrator unit a switch permits the selection of input resistors and feed-back elements in such a way that the unit can be used either as an integrator with scale factors ranging from 1 to 100 or as an amplifier with gains of from 10 to 100.

The limiter-amplifier unit, Figure 12, contains both a voltage limiter and a direct-coupled feed-back amplifier. The amplifier consists of two cathode-coupled stages, utilizing the two twin-triode tubes, V_3 and V_4. Feedback is accomplished by virtue of the differencing property of the first cathode-coupled stage. This method of feedback, essentially cathode feedback, results in a non-sign-changing amplifier.

The voltage limiter, which precedes the amplifier, consists of two diodes, V_{1a} and V_{1b}, biased positively and negatively, respectively, by two cathode followers. The amplifier input, therefore, is limited in both positive and negative polarity to approximately the voltages applied to the grids of the cathode followers. The method of biasing by cathode followers provides low source impedance without excessive drain from the power supplies and, at the same time, permits easy and continuous adjustment of the limiting level by variation of the grid potential. In this unit the grids are so driven as to cause symmetrical positive and negative limiting at a level varying from 0 to 100 volts.

In discussing displacement limiting in the preceding section, consideration was given to limiting in one direction only. Actually, however, the limiting in many systems occurs symmetrically, that is, for outputs both greater than $+\theta_s$ and less than $-\theta_s$. Consequently, in general, the quantity ϕ has the following form

$$\phi = \begin{cases} 0 & ; \ -\theta_s < \theta_o < +\theta_s \\ \theta_o - \theta_s; & \theta_o \geq +\theta_s \\ \theta_o + \theta_s; & \theta_o \leq -\theta_s \end{cases} \qquad (9)$$

Figure 17. Transient response of the simulated second-order system when subjected to a step input

Figure 18. Transient response of a displacement-limited servo

Figure 19. Displacement and negative velocity of a second-order system subjected to a step input, damping ratio of 0.1, velocity unlimited

Figure 20. Displacement and negative velocity of a second-order system subjected to a step input, damping ratio of 0.1, velocity limited to 0.5 times unlimited maximum

The essential features of the threshold circuit, which generates ϕ, appear in Figure 13. Diodes A and B of this circuit are biased as indicated so that unless θ_o is greater than $+\theta_s$ or less than $-\theta_s$ the output of the circuit is zero. However, if θ_o should become greater than $+\theta_s$, diode A will conduct, and because its plate resistance is very low compared to R_1 and R_2, its cathode will rise by the excess of θ_o over $+\theta_s$. The output in this case is $(1/2)\ (\theta_o - \theta_s)$. Similarly, if θ_o is less than $-\theta_s$, the output is $(1/2)\ (\theta_o + \theta_s)$.

In the displacement-limiting unit shown in block-diagram form in Figure 14, the effective limiting level is varied by changing the gain of that portion of the circuit between the input and the threshold circuit. The characteristic $(T_s p + 1)$ which equation 8 indicates is necessary for the formation of τ_s is produced by a feed-back amplifier having suitable feed-back networks. Stabilizing circuits similar to the one employed in the integrator unit are used in the two d-c amplifiers in this unit which provide the gain necessary for the simulation of the high natural frequency of the limit stop.

In most cases, the circuits described produce the desired limiting. Some conditions, nevertheless, momentarily require extremely high feed-back voltages which the final amplifier in the unit is unable to generate because of power-supply limitations. For example, if the voltage across the capacitor in the simple-lag network (see Figure 7) is large, corresponding to a high output velocity, a very large voltage of opposite polarity must be fed back to the network to reduce the capacitor voltage to zero quickly. This large feed-back voltage is analogous to the torque which the limit stop exerts instantaneously when struck by the output. If for any reason the high voltage called for cannot be applied to the net-

Figure 21. Displacement and negative velocity of a second-order system subjected to a step input, damping ratio of 0.1, velocity limited to 0.15 times unlimited maximum

work, a longer time is required to discharge the capacitor. Since the output cannot stop increasing until the capacitor voltage is zero, the limiting is not sharp and appreciable overshoot usually results.

As illustrated in Figure 15, an auxiliary switching circuit in the displacement-limiting unit alleviates this situation by placing a short circuit across the capacitor when the required feed-back voltage is higher than the final amplifier can produce. Position b is the normal position of the switch. However, when ϕ becomes sufficiently large, the switch is caused to move to either position a or position c, depending upon the polarity of ϕ. The diode thus connected across the network immediately discharges the capacitor; but because the short circuit is unilateral, the capacitor is free to charge in the other direction to permit the output to "back off" from the limit stop. The switch then moves back to position b and normal operation is resumed.

Information is transmitted within the main Dynamic Analysis and Control Laboratory computer almost entirely by means of 400-cycles-per-second amplitude-modulated suppressed-carrier voltages. Therefore the input and output units of the servo simulator perform the functions of demodulation and modulation for accepting and generating signals in this form.

Figure 22. Response of the displacement-limited servo to sinusoidal excitation

A. Displacement B. Velocity

Simulation of a Servo Limited in Velocity and Displacement

The second-order servo with limited velocity and displacement, for which the analog, Figure 7, has already been discussed, can be used as a simple example to illustrate the results obtainable by analog techniques. Combination of equations 1, 2, and 3 yields the following relation between input and output of the servo, valid when all variables are less than their limiting values

$$J_m \frac{d^2\theta_o}{dt^2} + B_m \frac{d\theta_o}{dt} + K_m\theta_o = K\theta_i \tag{10}$$

In operational notation this equation can be written

$$\frac{\theta_o}{\theta_i} = \frac{1}{\frac{p^2}{\omega_n^2} + \frac{2\eta p}{\omega_n} + 1} \tag{11}$$

in which the natural frequency

$$\omega_n = 2\pi f_n = \sqrt{\frac{K_m}{J_m}} \tag{12}$$

and the damping ratio

$$\eta = \frac{B_m}{2\sqrt{K_m J_m}} \tag{13}$$

Figure 16 shows the theoretical response, computed from equation 11, of such a system when subjected to a suddenly applied input of fixed displacement. Curves are shown for several values of ω_n and ζ, all obtained by holding fixed the time constant, $T_m = J_m/B_m$. An electric analog was constructed from the simulator components described previously according to the arrangement shown in Figure 7. The response of this analog under conditions corresponding to those used in calculating Figure 16 is given in Figure 17. None of the quantities reached its limiting value in these tests; hence the response should be that of a completely linear second-order system. Comparison of Figures 16 and 17 demonstrates that there is very close agreement between the response of the analog and the theoretical behavior. (The minor ripples superimposed on the curves of Figure 17 are due to malfunctioning of the cathode-ray oscilloscope from which the photograph was taken.)

Displacement limiting of the servo is illustrated in Figure 18, which shows the analog output as a function of time. Curve a is the same as that shown in Figure 17 for a damping ratio, ζ, of 0.1.

Figure 23. Velocity versus displacement when the displacement is unlimited and when it is limited to 0.75, 0.5, and 0.25 times its unlimited value

Curves b and c represent the behavior of the same system when the displacement is limited to slightly greater and slightly less, respectively, than the magnitude of the displacement called for by the input. Both curves indicate that the output comes to an abrupt halt upon striking the displacement limit. At that point, when the input is less than the limit, as in curve b, the error signal is in the direction to cause the output to decrease. Therefore, since the velocity has been reduced to zero, the motion of the output immediately reverses. The remainder of the curve is the response of the linear system when subjected to a negative step input equal in magnitude to the difference between the limit and the displacement originally required. When the displacement is limited to less than that demanded

Figure 24. Velocity versus displacement when the velocity is unlimited and when it is limited to 0.75, 0.5, and 0.25 times its unlimited maximum

by the input, as in curve *c*, the error is such as to maintain the output against the limit continually.

Figures 19, 20, and 21 show simultaneously the output position and the negative of the velocity of this system. Figure 19 is again the response of a linear second-order system with a damping ratio of 0.1; in Figures 20 and 21, respectively, the velocity is limited to approximately 0.5 and 0.15 times the maximum velocity attained by the unlimited servo. In the latter two cases the response is exactly the same as that of the linear servo until the maximum permitted velocity is reached. The output displacement then increases at a constant rate until the error signal is less than that required to maintain the maximum velocity. From that point on, the response, again that of a linear second-order servo, may be calculated from equation 9 with the proper initial conditions.

The response of the displacement-limited servo to sinusoidal excitation is shown in Figure 22 (A). In this particular case, the displacement is limited to half of the maximum value which would be produced by an unlimited servo having the same input. The corresponding velocity is plotted in Figure 22(B). These illustrations show clearly that the velocity is reduced almost immediately to zero when the output reaches the limit. During the time that the error signal is sufficient to maintain the output against the limit, the velocity remains zero; then, when the sign of the error reverses, the velocity begins to build up in the opposite direction causing the output to leave the limit.

An interesting and useful means for presenting the information contained in Figure 22 is the so-called "phase-plane" diagram, in which velocity and displacement are plotted against each other. Such a presentation is shown in Figure 23, vertical distances representing velocity and horizontal distances, displacement. The circular trace, *a*, represents the system under sinusoidal excitation with no limit on the displacement, that is, when the system is operating linearly. Consequently, both displacement and velocity are sinusoidal; and since velocity is the first time derivative of displacement, the two quantities differ in phase by 90 degrees. The resulting graph, which can be made to appear circular by proper choice of horizontal and vertical scales, is traced in a clockwise direction, once for each cycle of the excitation.

Figure 25. Frequency response of the simulated second-order servo

The other traces of Figure 23 are obtained by plotting similarly the velocity and displacement of a displacement-limited servo. The velocity and displacement of Figure 22, for example, when plotted along the vertical and horizontal axes, respectively, produce trace *c*. Figure 24 is a similar representation of a velocity-limited servo. All the trajectories in both of these figures are traced in a clockwise direction; in each diagram the scales are exactly the same for all traces.

Accuracy of the Simulator

When compared with the theoretical responses given in Figure 16, the measured linear transient responses, shown in Figure 17, indicate that the accuracy of simulation is good. A better measure of the accuracy of simulation over the linear range is obtained from steady-state frequency-response tests with the simulator components arranged to represent a second-order system as in Figure 4. The test results shown in Figure 25 indicate that the measured responses agree with the theoretical responses with an error of less than 1 per cent at the natural frequency. When the input and output units are added to the system, the tests made on a carrier basis give results comparable to those shown in Figure 25, except at frequencies above 25 cycles per second where the measured phase angles are larger than the theoretical values principally because of the filter used in the output unit.

The stability of the gain-determining resistance and capacitance components in the units is high so that more accurate results are obtainable from the equipment by calibrating each unit in comparison with a higher accuracy standard. Noise and drift in the units have been held to less than 0.1 per cent of full scale.

In simulating nonlinear effects, the errors in limiting levels are in general not more than 1 per cent of the maximum levels of the circuits employed. Operation at high levels, therefore, minimizes these errors.

The system chosen for illustration purposes was made simple intentionally to facilitate comparison of its theoretical linear behavior with the simulator response. Aside from its use in conjunction with the principal Dynamic Analysis and Control Laboratory computer, the servo simulator will be of greatest use in studies of more complex systems, particularly those containing nonlinearities, for which analytical treatment is impractical. For these systems, analog techniques such as are described in this paper represent a simple and direct means for obtaining solutions to the associated problems of design and analysis.

Discussion

Gerald Landsman (National Bureau of Standards, Washington, D. C.): The use of a flight simulator as a tool in the design and engineering of an aircraft control system, as contrasted to its use as a research and development tool, should be strongly emphasized. System and component engineering in an aircraft control system is facilitated to a surprising degree, if the control system is employed directly with its simulated airframe at every possible phase of engineering. Extensive use of this technique by the National Bureau of Standards has shown it to be an extremely useful tool.

In such a program of design and engineering, it is often found that the limiting features of the control system design are in the nonlinearities associated with the control system "hardware." Two major lines of attack may be followed in designing a control system in the presence of these nonlinearities.

The first involves the direct testing of the control system on the flight simulator with observations being made of the over-all airframe plus control system performance. These observations are then compared with

the results of system simulation with the autpoilot being considered a linear device to determine the acceptability of the control system design and engineering. However, in many cases, control systems are characterized by a large number of nonlinear elements. In such cases, the first line of attack is rendered extremely difficult and recourse must be made to a second line of attack. This involves the step-by-step simulation of control system nonlinearities. This nonlinearity simulation is accomplished by the methods so effectively developed in this paper.

An alternate method for the simulation of "dead space" to that indicated in Figure 13 of the paper is shown in Figure 1 of the discussion. It is possible with this method to avoid building extra units of the type indicated in Figure 13 and to use instead already

Figure 1. Threshold Circuit

available summing, inverting, and limiting amplifiers. Use of limiting amplifiers, as indicated in Figure 12, or by equivalent sharp cut-off circuits, has the advantages of sharper limiting characteristics plus the easy and continuous adjustment of the limit level mentioned in the paper. This method of threshold simulation may be easily employed by laboratories using many of the commercially available analogue computers.

C. M. Edwards and E. C. Johnson, Jr.: Mr. Landsman's alternative threshold circuit is a good suggestion for a way to obtain the characteristics of a dead space using standard analogue computing elements. Furthermore, it indicates the flexibility of analogue techniques by which a large variety of physical phenomenon can be simulated with different arrangements of a few basic units.

In some cases it may be more economical of space and expense to construct special units for a particular simulation problem rather than to use the existing standard units.

Limit stop simulation is almost always required in servo problems, therefore development of the special displacement limiting unit was carried out using the threshold circuit shown in Figure 13.

A Generalized Analogue Computer for Flight Simulation

ALBERT C. HALL
MEMBER AIEE

THE effort devoted to the development of aircraft up to the present has been directed largely toward the improvement of performance factors such as range, cruising speed, economy, operating altitude, and so forth. These factors in a particular case are determined primarily by the steady-state operating characteristics of the aircraft. On the other hand, factors such as maneuverability, speed of response, ease and accuracy of control, involve the dynamic properties of the aircraft and have received relatively little consideration. However, with the advent of higher flight speeds and increasing interest in automatically-controlled aircraft, dynamic problems are becoming of much greater importance, and in some applications are predominant in significance.

The mathematical solution of aircraft dynamic problems is characterized by considerable complexity due partly to the high order of the differential equations involved and particularly to the nonlinear nature of the equations. Nonlinear effects are introduced by the kinematics of rigid bodies with several degrees of freedom, the physical nature of the aerodynamic forces, and peculiarities of equipment provided to control the flight. The complexity is such that general solutions are not known and few specific cases have been solved without drastic assumptions.

Most of the mathematical analysis of aircraft dynamics has been devoted to the study of the so-called "linearized" equations. Here assumptions are made that eliminate the nonlinear effects and permit the problem to be represented by linear differential equations. Physically, these assumptions require that the motion of the aircraft be limited to infinitesimal departures from the steady-state condition, that a number of aerodynamic effects be neglected, and that the operation of any control system involved be restricted to the linear range. Even in cases where these drastic assumptions are permissible, however, the analysis is complex because of the high order of the differential equation and consequently most of the work has been limited to specific cases. While the study of the linearized equations has been of great value, the solutions are of limited usefulness because of the restrictive nature of the underlying assumptions.

The high order of the equations and the existing state of knowledge of nonlinear differential equations lead to the conclusion that the only practical method of solution of most aircraft dynamic problems is by means of computing machines. Unfortunately, the complexity of the problems is such that no existing computing machine was well suited to the solution of many urgent problems. Because of this need the Dynamic Analysis and Control Laboratory at the Massachusetts Institute of Technology undertook the development of a generalized analogue computer to contribute specifically to the solution of aircraft dynamic problems. The development was sponsored by the Bureau of Ordnance, Department of the Navy. The principal development problems and the salient characteristics of the analogue computer, which is presently in operation, are the subject of this paper.

While the design of the computer was generalized as much as possible in order not to restrict unduly its application to the broad field of computation, most of the machine specifications were determined by the requirements of aircraft dynamic problems, and for this reason the computer is called a flight simulator. The general characteristics desired in the computer are: reasonably high accuracy; considerable capacity for ordinary mathematical operations such as addition, multiplication and integration; special faculty to represent a sizable number of nonlinear effects, particularly of the trigonometric type; and high speed of computation. Means of securing these characteristics are discussed in this paper. The analogue computer also was planned for the dynamic testing of control systems employed in the automatic operation of aircraft. It is in this application of the flight simulator that high speed of computation is particularly important. In such applications the machine must compute on a 1-to-1 time scale, that is, it must compute the solution to an aircraft problem in exactly the time required for the process to occur in the physical situation. If such speed is achieved and proper auxiliary equipment made available, it is possible to simulate a flight problem by setting up the computer to represent

Paper 50-48, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1950. Manuscript submitted November 3, 1949; made available for printing November 30, 1949.

ALBERT C. HALL is with the Massachusetts Institute of Technology, Cambridge, Mass.

The author wishes to acknowledge the many helpful contributions from a number of engineers. The mechanical design of the flight table was carried out by Jackson and Moreland, Boston, and its fabrication was the responsibility of the Palmer-Bee Company, Detroit. The systems engineering of the computer was under the supervision of C. M. Edwards, and his contributions in this respect as well as those of L. C. Dozier, H. Jacobs, and G. H. Hart should be noted. Component development in general was directed by E. St. George and in this category the contributions of W. W. Seifert and M. T. Weiss on the repeater amplifier and summing network, W. J. Deerhake and A. Fuchs on the integrator, C. H. Woods on the multiplier, and B. B. Crocker on the arbitrary function generator, are particularly noteworthy. The hydraulic servo development is to the credit of J. F. Blackburn (also responsible for much of the flight table development) with effective contributions from I. Kotlier. The work of R. W. Bond, H. E. Blanton, and S. B. Williams on the flight-table servomechanisms must be mentioned and effective contributions in the development of the flight-table instrumentation were made by R. D. Atchley on the angular accelerometer, and W. G. Andrew, E. St. George and E. P. Blanchard on the rate gyroscope. Important detailed contributions, too numerous to list, were made by T. F. Jones, R. E. Kimball, F. C. McCoy, J. McHoul, and H. Price.

Figure 1. Comparison between the purely computational and the testing functions of the flight simulator

Figure 3. Simulator diagram for computer solution and component testing for a roll stabilized aircraft

the aircraft dynamics, employing the aircraft control equipment in a fashion analogous to that in which it is used to control the actual aircraft, and making use of auxiliary equipment to link the control equipment and the computer. This method of operation permits the dynamic performance of the aircraft control equipment to be tested under conditions closely similar to actual flight.

Topics in Aircraft Dynamics

While by no means restricted to such problems, the analogue computer was designed specifically to solve problems in the field of aircraft dynamics. Certain features of the machine, therefore, such as the auxiliary equipment required for the testing of aircraft control systems, are of limited application. In general, however, problems in aircraft dynamics are sufficiently varied that little compromise in versatility need or can be made. A few of the principal topics in aircraft dynamics are described and it may be seen that the problems contain elements common to dynamic problems in a variety of fields.

Stability and Transient Properties of Aircraft

An important consideration in the operation of aircraft is the stability characterizing its motion. The aircraft in general should be stable; that is, transient motions caused by gusts or motion of the control surfaces should decay rather than continue or build up. Moreover, most applications require that these transients decay at prescribed rates. Under some conditions these questions can be answered by analytical means alone. More often analytical procedures become cumbersome and the use of mechanical computation is advisable. Frequently the size of the disturbances is sufficiently large and the inherent nonlinearities so important that the use of a computer to solve for the transient motions of the aircraft is mandatory.

Design of Aircraft with Prescribed Dynamic Characteristics

While relatively little effort has been devoted in the past to designing aircraft with carefully specified dynamic properties, applications are arising which require close control of the dynamic performance. An analogue computer is of great use in such an undertaking if it permits ready variation of the design parameters since a rapid study can then be

Figure 2 (left). Stabilization of an aircraft in roll

Figure 4 (right). Floor plan of the flight simulator

Figure 5 (left). Aerodynamic computer

Figure 8 (right). Summation network

made of the dynamic properties of a variety of aircraft configurations. The computer should be of considerable range in order to represent the so-called second order effects. These effects are generally omitted in analytical studies but must be considered if good correlation is to be obtained between the predicted characteristics and those determined from flight tests.

Control System Synthesis

An important topic in aircraft dynamics is the synthesis of automatic pilots to obtain prescribed over-all response characteristics in the controlled aircraft. In applications of this sort a portion (generally the aircraft characteristics) of the control system is specified. The problem is to determine the necessary properties of the remainder (generally the autopilot) of the control system that will provide the response desired in the over-all system. Problems of this sort are closely related to the topics discussed above, except for the emphasis on the control system rather than the aircraft. In complex problems, synthesis procedures are developed by solving sufficiently numerous and diverse problems that patterns in the solutions can be recognized. Synthesis problems require speed and flexibility in the operation of the computer in order to solve quickly the required large number of specific cases.

Control System Test

Peculiarities in autopilot equipment make it desirable to test thoroughly the performance of the control system prior to installation in the aircraft. Simulation of the flight conditions by means of the analogue computer makes it possible to test the control components in the laboratory if auxiliary equipment described in the following paragraphs is employed. This type of operation requires the solution of the problems on a 1-to-1 time scale, and therefore only a restricted range of problems can be solved. However, it has been found that the important dynamic properties of a wide range of sizes of aircraft fall within a limited area and this fact makes it feasible to test the control systems of a variety of aircraft with a single type of computer.

Mathematical Characteristics of Problems in Aircraft Dynamics

The type of equation that is encountered widely in problems in aircraft dynamics is the nonlinear ordinary differential equation with varying coefficients with time as the independent variable. Partial differential equations are encountered less often and frequently can be approximated adequately by ordinary differential equations. The scope of the equations generally required is discussed in the following.

Order of the Equation

The highest order differential occurring in the general equation of motion can be between 20 and 30 (or higher) depending upon the complexity of the control system and the number of second order effects considered. If the motion being studied is that of a rigid body in space with unrestricted motion the system has six degrees of freedom and the order of the differential equation is 12 even though no aerodynamic forces act upon the body. If the aircraft is automatically controlled in the conventional manner by regulating the roll, pitch, and yaw orientation angles of the aircraft, the many dynamic effects introduced by the control system require a very high order of differential equation to represent the situation.

Nonlinear Terms

The number of nonlinear terms which require representation in aircraft dynamic problems is difficult to specify, and such a number is not particularly meaningful since some nonlinear effects are more troublesome than others to represent in an analogue computer. Problems are frequently encountered in which 20 terms in the equations require nonlinear representation. Some of the effects appear

Figure 9 (left). Functional diagram of the repeater amplifier

Figure 11 (above). Application of the variable induction principle to vector resolution

as products of dependent variables, many arise as trigonometric functions, and others appear as arbitrary functions of dependent variables determined experimentally. The principal nonlinear effects are produced by the basic dynamic phenomena of a rigid body with six degrees of freedom, by the nonlinear nature of most aerodynamic effects, and by saturation and dead space peculiarities of the autopilot. Some of the effects can be represented in the computer by forming products of variables or by trigonometric functions. However, many cannot be analytically expressed in closed form and must be approximated by suitable means in the computer. Many of these nonlinear effects are known to be important to represent and to study. In other cases their importance is unknown but must be determined by computing-machine study.

Trigonometric Functions of Dependent Variables

An important source of complexity in aircraft dynamics is the large number of trigonometric functions present in most problems. Although trigonometric functions are nonlinear effects and as such have been mentioned before, their importance warrants special consideration. Trigonometric functions are introduced principally by the fact that the aerodynamic forces and moments acting upon an aircraft are best expressed relative to a coordinate system fixed in the aircraft while other effects, such as those produced by gravity and those initiated by reference elements such as unrestrained gyroscopes, operate in a co-ordinate system fixed in space. This difference in basic co-ordinate systems requires several transformations of vectors between sets of axes and consequently a number of trigonometric functions are required for mathematical representation. The complications thus introduced are substantial and it is necessary to choose processes of computation well adapted to handling these effects. A study of problems encountered in aircraft dynamics indicates that it is frequently necessary to transform as many as nine vectors between sets of three dimensional co-ordinates.

Dynamic Testing of Control Components

As indicated before, the flight simulator is designed to be employed in two general ways. In the first method of operation, the problem is defined completely in equation form and the computer is set up to solve the equations. In the second method of operation, the flight control components are employed with the computer in a fashion analogous to that in which they are used in flight.

Figure 1 compares the two methods of operation. When the analogue computer is used to represent completely the problem, the aircraft properties and the control system characteristics both must be determined and mathematically formulated. The computer is set up in accordance with the formulation, and the solution determined. However, if the flight simulator is used to test the control components, only the aircraft properties and the flight conditions need be formulated mathematically. The analogue computer is set up in accordance with this formulation as in the first method of operation. The properties of the control components do not have to be represented by the computer since the actual components are employed in obtaining the problem solution. The combination of the computer and the flight control system comprises the analogue of the problem. The advantage of using the flight simulator in the latter fashion lies in the fact that the machine representation of the control system is unnecessary. Many of the control systems in use and envisioned are complex and their operation not completely understood. The nonlinear and dynamic features of the control system are frequently such that the results of any test is open to question unless the system is used in exactly the situation for which it was designed. Even when the control system properties are known with sufficient accuracy their machine representation often is not easy. Accurate formulation of the control system may require a differential equation of tenth or higher order; moreover, certain types of nonlinearities which occur frequently are difficult to represent accurately in an analogue computer.

Figure 10. Repeater amplifier

The principal technical problem raised by the testing of control components in the flight simulator is the high speed of computation required of the computer. It is not feasible to make a time transformation in order to "slow down" the problem because the computational process must take place at the same rate as the physical process in order to subject the control components to the proper test. Therefore the dynamics of computation must be considered carefully, and the various extraneous time-lags always as-

Figure 12. Resolution of a vector in the analogue computer

Figure 13. Block diagram of the integrator

sociated with computation must be reduced to a point at which they are insignificant relative to the dynamic effects of the problem if accurate results are to be secured.

The use of the analogue computer as either a computational device alone or alternatively as a testing device is illustrated by a simple example. Suppose the problem at hand is a common one, namely, the study of the stabilization of an aircraft in roll. The physical situation is illustrated by Figure 2. The orientation of the aircraft relative to axes fixed in space is denoted by ϕ_o. A correcting moment is applied to the aircraft by means of a pair of ailerons the angular deflection of which, relative to the neutral position, is denoted by δ. The ailerons are operated by a control system employing a vertical gyroscope as the reference element.

If a number of assumptions are made, such as that of no coupling between the other motions of the aircraft and its roll motion, the dynamic equations can be written as follows

$$L_\delta \delta + d = I_x \frac{d^2\phi_o}{dt^2} + L_p \frac{d\phi_o}{dt}$$

$$\delta = f(\phi_I - \phi_o)$$

In these equations

I_x = moment of inertia of the aircraft about the roll axis
L_p = damping coefficient
L_δ = coefficient of the control surface moment
ϕ_I = desired orientation of the aircraft

The first of the foregoing equations is the equation determining the aircraft roll motion and the second is the equation for the operation of the control system. The control system measures the roll angle ϕ_o, compares it with the desired orientation, and if required, produces a correcting motion of the control surfaces.

The study of this problem on the flight simulator with the control system components either simulated or operating is illustrated in Figure 3. One portion of the illustration shows how the aerodynamic equation is represented in the computer. Machine operations of summation, integration, and multiplication are indicated by the corresponding mathematical signs. If the analogue computer is to simulate the control system a second part of the computer must be set up and in Figure 3 this is indicated in block form only, since the control equation has not been specified. If the selector is in position one and the appropriate initial conditions are imposed, the computer is ready to solve the problem. An example of a typical problem is the determination of the roll angle ϕ_o as a function of time when a disturbance d, such as might be caused by a gust, is applied.

The second use of the simulator illustrated in Figure 3 is the test of the actual flight control unit. Auxiliary equipment, comprising a flight table and controlling servomechanism, is required in order to orient any reference element of the control unit, such as a gyroscope, in a manner corresponding to that occurring in flight. The reference element and the remainder of the flight control unit are interconnected in the way normally employed in flight, and the shaft or other type of mechanical output connecting the control unit to the ailerons may be loaded mechanically to simulate the effect of bearing friction, the mass of control surfaces, and the wind loading encountered in flight. The displacement of the output is measured by suitable means, such as a potentiometer, and the electrical signal supplied to the computer through the selector which is set in position 2. This method of operation provides as realistic a test of the control unit as may be had without actual flight.

The technical problems introduced by operation of the analogue computer to test flight components are associated for the most part with securing proper dynamic characteristics in the computer and the auxiliary equipment. The necessity of computing rapidly in order that the problem may be run on a 1-to-1 time scale has been pointed out. Dynamic effects in the flight table and its servos are equally important and are even more troublesome to control because of the dimensions and weight of the physical equipment required to carry and orient the flight components.

System Considerations

Computer Elements

The analogue computer consists of an array of computing elements, each of which carries out a particular mathematical operation, and associated equipment for so interconnecting the elements that the combination provides a representation or analogue of the problem being studied. Computing elements are provided for carrying out such mathematical operations as addition or subtraction, multiplication, integration, and trigonometric transformation. The operation of differentiation is not performed as a transformation of the equations characterizing the problem always make this operation unnecessary.

A description of each of the computer

Figure 14. Integrator

Figure 15 (above). Multiplication by means of a potentiometer

Figure 17 (right). Linear approximation to an arbitrary function

elements is given in another section of the paper.

Analogue of the Dependent Variable

A basic consideration in the design of an analogue computer is the means of representing in the machine the dependent variables of the problem. In general the machine analogue of the dependent variable can be an electrical signal or mechanical motion and frequently is the former in one portion of the computer and the latter in another portion. While analogue computers have been built in which the analogue quantity is a mechanical rotation or displacement throughout, such machines are less flexible than ones in which electrical signals alone, or both electrical signals and mechanical motions, are employed to represent variables.

If the machine variable is an electrical quantity, it may be a direct voltage proportional in magnitude and sign to the magnitude and sense of the corresponding dependent variable of the problem. The electrical signal also may be an alternating voltage of fixed frequency, the magnitude of which is proportional to the magnitude of the dependent variable and the phase of which is either zero or 180 degrees for positive or negative senses respectively of the dependent variable. The latter or a-c method was chosen for the computer described here, and the computer, therefore, is frequently called an a-c computer.

Among the advantages of the a-c type of computer are feasibility of employing a-c amplification and the corresponding freedom from drift and grounding problems encountered when d-c amplification is required; and simplicity with which trigonometric resolution is performed. The principal disadvantage of an a-c type analogue computer is the meticulous attention that is required to prevent phase shift difficulties. In this computer it was necessary to limit the phase shift occurring in each computation such as multiplication by a constant, addition, and so forth, to 0.05 degree, and to employ so-called quadrature rejection circuits in the integrators to render them insensitive to small phase shifts. The accuracy of computation is not affected directly by small phase shifts in the a-c signals, but overloading in amplifiers may occur with ac-

Figure 16 (below). Electromechanical strain-gauge multiplier

Figure 18 (right). Arbitrary-function generator

companying deterioration of performance. Phase shifts in the computer are minimized by using interconnecting cables of low capacitance, and driving long lengths of cable with low output impedance repeater amplifiers.

A frequency of 400 cycles per second is chosen for the a-c signals. Choice of a high frequency minimizes many of the time lags inherent in an a-c computer and permits the size of certain of the computing elements to be reduced. On the other hand, phase shift difficulties are larger for a higher frequency signal. The frequency chosen is a compromise between these two considerations.

Certain computing elements have a rectilinear or rotational motion for their output and here mechanical displacement is the analogue of the dependent variable. Unlike certain of the differential analyzers, however, mechanical displacement is not transmitted from one point to another in the machine. Only electrical signals are transmitted over appreciable distances.

Specifications on Computation Accuracy

An important problem in the development of a large scale analogue computer is the determination of the accuracy with which individual machine operations must be carried out. It is convenient to use the term "accuracy" to refer to the static or steady-state condition. Dynamic effects, which are equally important, are considered separately. Exact determination of the required accuracy does not seem to be feasible without detailed knowledge of the specific problems to be solved. Since, in general, such information is not available at the time the machine is constructed, other means must be employed to determine the necessary accuracy. An estimate of these requirements can be made on the basis of the following argument. If the machine is set up as an exact analogue of a physical process there is a point by point correspondence between operations of addition, integration, multiplication, and so forth, in the computer and the analogous operations in the physical process represented by the machine. If each computer operation is carried out to an accuracy and order of magnitude greater than the corresponding operation occurs in the physical process due to uncertainties in the physical parameters, it can be expected that the errors in the machine solution will be small compared to the divergence of results caused by physical uncertainties.

Therefore, if the analogue computer is to be employed to solve problems in which the parameters are known to a few per cent, an accuracy of a few tenths of one per cent in each machine operation should be sufficient. In a vast number of physical problems the parameters are not known to better than one per cent and this is certainly true for the majority of problems in flight dynamics. Consequently it was decided to set the allowable error for each computer element at 0.1 per cent of maximum.

The above argument should not create a false sense of security as far as accuracy considerations are concerned. It is frequently necessary to so transform the equations of the problem that a point by point correspondence with the physical process no longer exists. This is particularly true of the type of machine described here which does not perform the operation of differentiation although an analogous operation can occur physically, approximately at least. For these and other reasons each individual problem must be considered carefully when it is studied with the machine in order to obtain an estimate of the solution accuracy.

Dynamic Effects

The dynamic effects associated with each computer-element operation are equal in importance to steady-state accuracy considerations in affecting the correctness of the solution. No physical device will carry out such ideal operations as addition, integration, and so forth, with no associated time delay. If these time delays are too large the machine no longer can be considered as an analogue of the problem being studied and the machine solution will bear no observable relation to the true solution. The setting of allowable time delays is a difficult problem, but in general it can be shown that the time delays occurring in machine computation will have a negligible effect on the solution provided they are small relative to characteristic times, such as periods of oscillation, in the solution. Each problem must be considered separately, however, to assure a correct solution.

If the machine time lags are not small relative to the problem, they can be made so by transforming the time variable effectively to "stretch out" the solution, provided the computer is not required by other considerations to operate on a fixed time scale. If it is so required, as when the simulator is used to test control components, those problems must be excluded in which events take place so rapidly that the computer dynamic effects become predominant. Considerations such as these determined the allowable time lags of each computer element.

Physical Arrangement of the Flight Simulator

The floor plan of the simulator is shown in Figure 4. The computer, which is housed in racks on one side of the room, is separated into two portions. One portion, called the aerodynamic computer, is set up in a relatively invariable form to solve the set of aerodynamic equations that represents the usually considered effects. Figure 5 shows the major portion of this section of the computer. The remainder and larger part of the computer, called the generalized computer, is set up in flexible form to solve general equations of the type discussed early in this paper and is not limited to aerodynamic problems. However, the generalized computer is used for representing the less ordinary types of aircraft dynamic phenomena and in such problems it is interconnected with the aerodynamic computer.

Interconnections in the generalized computer are made by plug board arrangements. In both computers all components are of the plug-in type to obtain the maximum flexibility both in operation and maintenance. A rack of the generalized computer is shown in Figure 6. This rack contains an integrator and other computing elements normally associated with it. Interconnections among equipment in the rack are made at the top. The rack also contains calibration equipment, and, located at the bottom, the regulator for the direct current power required. Each rack has its own regulator in order to eliminate difficulties caused by common ground returns.

Recording and control equipment are located adjacent to the flight table which is described in another section of the paper. Figure 7 shows this section of the equipment. Also available are two 2-pen plotting boards manufactured by Electronic Associates Inc., with special high-speed pen drive servomechanisms developed at the Dynamic Analysis and Control Laboratory.

Computing Components

The machine operations required in the flight simulator are separated into the familiar ones of summation, integration, multiplication, trigonometric transformation, and nonlinear representation. No claim for originality is made for most of the methods of computation employed and some of the basic ideas (summation by resistive networks, for example) are

quite old. However, considerable development was necessary to secure components that realized the accuracy specification of 0.1-per cent error and the required dynamic performance. Because of the necessarily general nature of this paper it was felt that its usefulness would be little enhanced by references to the somewhat extensive literature. Other papers in preparation will discuss the more important components in detail and provide references to prior work. The salient features of each type of computing component is discussed below.

Summation Network

Operations of addition and subtraction are carried out in the computer by means of resistive networks illustrated in principle by Figure 8. When the problem requires that variables be added they are represented by electrical voltages and applied to the input of the network illustrated. The output voltage is proportional to the sum of the inputs multiplied by an attenuation factor which is a function of the magnitude of the resistors and the number of voltages being summed. The attenuation factor is constant for a particular network and is considered as a calibration constant. Networks are provided in the computer for adding up to eight signals, and additional signals can be summed by cascading summation networks properly separated by buffer amplifiers.

The accuracy of summation is a function of the accuracy and stability of the resistors in the network, as well as any variations in the source and load resistances of elements preceding and following the summation network. Over long periods of time the accuracy is a little better than ±0.1 per cent. The time lag associated with summation operations is determined by the reactive parameters of the network as well as those of the source and load elements. The effective time constant is below one-tenth millisecond.

As mentioned before, phase-shift in the a-c signal is troublesome and must be controlled. The stray inductances of the elements of the summation network would cause excessive phase-shift were not a compensating effect introduced by means of the trimming capacitances shown in Figure 8.

Repeater Amplifier

A number of amplifiers are required in the analogue computer for purposes such as multiplication by a constant, compensating for attenuation occurring in computer elements, buffer purposes, and as

Figure 19. Gimbal frame

low impedance sources. For example the summation network described in the preceding section should be followed by an element with high input resistance. Such networks, therefore, are usually followed by a repeater amplifier that not only serves as a high resistance load, but also makes up for the attenuation that occurs in the network. If the repeater amplifier is designed to have a low output resistance, long lengths of signal transmission cable can be connected to its output terminals without introducing excessive phase-shift. Indeed, the importance of minimizing phase shift makes it desirable to provide an impedance changing amplifier following any high resistance circuit if more than a few feet of cable are required to connect the circuit to the next element in the computer.

A repeater amplifier was developed to meet these and other needs of the computer. It was desirable that the number of types of amplifiers be kept small to minimize servicing difficulties and it was found possible to meet most of the repeater amplifier requirements with one basic type. Special effort was needed to insure that the gain stability of the repeater amplifier was commensurate with the accuracy specifications of the computer. Other requirements are good dynamic properties, small phase shift, flexibility of application, and reliability. The last requirement is particularly important because of the number of such amplifiers (more than 200) required in the computer.

The block diagram of the amplifier developed to meet the foregoing requirements is shown in Figure 9, and Figure 10 is an illustration of the unit. The gain of the amplifier is nominally ten although gains of one, two or five also can be selected by means of the attenuator. The necessary gain stability is achieved by means of the negative feed-back feature. The gain around the feed-back loop is at least 1,000 and by limiting the over-all gain to ten, high gain stability is obtained in spite of large changes in tube characteristics. The phase shift of the amplifier at the signal frequency is kept within ±0.05 degree. In addition, the slope at the operating frequency of the phase shift versus frequency characteristic is such that the time lag of the amplifier is well below 0.1 millisecond.

The input resistance of the amplifier is one megohm, and by employing a specially designed transformer in the output a choice of output resistances of either 75 or 10 ohms output impedance is available. Either or both senses of the output signal is available thus allowing ready multiplication by minus one.

Another feature of the amplifier is the overload indicator indicated in Figure 9. The linear range of the amplifier is better than 100,000 to 1, but overloads can occur if the problem set-up is incorrect. If overload occurs in the process of a problem solution, an erroneous answer is almost certain to result. By triggering a gas triode if the amplifier signal exceeds a predetermined level the overload indicator provides the operator with a warning that the linear range of the amplifier may have been exceeded.

Vector Resolver

The number of trigonometric functions appearing in problems of the dynamics of rigid bodies has been mentioned. These functions for the most part are introduced by the need to transform vector quantities from one set of axes to another. It is important, therefore, that the analogue computer be capable of carrying out vector resolution with accuracy and facility. The fact that the computer employs a-c signals to represent the dependent variables makes it possible to apply the variable induction principle to carry out vector resolution, and in fact this was one of the major reasons for deciding on the a-c type of computer.

The variable induction principle applied to vector resolution is illustrated in Figure 11. The resolver comprises a pair of stationary coils in space quadrature and a pair of movable coils that can be rotated relative to the stator. If voltages V_1 and V_2 are applied to each of the stator coils and the angular displacement of the rotor relative to the stator is the angle θ as shown in the figure, the voltages induced in the rotor have the following expressions

$$V_3 = K(V_1 \sin\theta + V_2 \cos\theta)$$
$$V_4 = K(V_1 \cos\theta - V_2 \sin\theta)$$

In these equations V_1, V_2, V_3, and V_4 are the amplitudes of sinusoids, and the coefficient K is a constant calibration factor.

The device illustrated in Figure 11 is called a resolver, and the availability of such a computing element makes it feasible to carry out relatively complex trigonometric resolutions. Consider the common problem in which it is necessary to determine the components of a vector with respect to one set of three orthogonal axes when the components are known with respect to an independent set of axes. This problem is frequently encountered in aircraft dynamics, where, for example, the velocity of the aircraft may be known with respect to axes fixed in the aircraft, but must be resolved into components measured relative to earth axes. If the components of the vector, V_x', V_y', and V_z', measured with respect to axes X', and Y', and Z', are known and the vector components V_x, V_y, and V_z, relative to axes X, Y, and Z, are to be determined the following are the transformation equations

$$\begin{aligned}
V_x = {} & V_x'(\cos\psi \cos\theta) + V_y'(\cos\psi \times \\
& \sin\theta \sin\phi - \sin\psi \cos\phi) + \\
& V_z'(\cos\psi \sin\theta \cos\phi + \sin\psi \sin\phi) \\
V_y = {} & V_x'(\cos\theta \sin\psi) + V_y'(\sin\phi \sin\theta \times \\
& \sin\psi + \cos\phi \cos\psi) + \\
& V_z'(\sin\theta \cos\phi \sin\psi - \sin\phi \cos\psi) \\
V_z = {} & V_x'(-\sin\theta) + V_y'(\cos\theta \sin\phi) + \\
& V_z'(\cos\theta \cos\phi)
\end{aligned}$$

The angles θ, ϕ, and ψ are the Euler angles that locate the axes X', Y', and Z' relative to X, Y, and Z. Figure 12 is a diagram of one means of carrying out this resolution in the computer. It is frequently necessary to resolve several vectors from one set of axes to another, and this figure is illustrative of the complexity involved.

The resolver employed in the analogue computer is one developed by the Arma Corporation. The accuracy of resolution is approximately 0.1 per cent, and while the time constant has not been measured directly it is expected to be below 0.1 millisecond. Each of the stator coils must be excited from a low impedance source and a version of the repeater amplifier described earlier is employed for this purpose. The resolver is shown among the instruments in Figure 20.

Integrators

Perhaps the most important single element in the analogue computer is the integrator. The type of unit employed most widely in the flight simulator in principle is essentially a velocity servomechanism and is shown in block diagram in Figure 13. In order to describe the method of operation suppose the integral with respect to time of a variable V_1 is desired. The computer signal $V_1 \cos \omega_c t$ is applied through a summing network and an amplifier to the control field of a 2-phase induction motor, the second or reference field of which is excited with a sinusoidal voltage of angular frequency ω_c and of constant amplitude. The motor revolves in response to the voltage on its control field and turns the rotor of an induction generator to which it is coupled mechanically. The induction generator is in principle a 2-phase induction motor with only one field excited. A voltage, $V_2 \cos \omega_c t$, appears at the terminals of the second field if the rotor of the induction generator is revolved, and with careful design of the generator characteristics, and constant generator excitation, the amplitude V_2 can be made accurately proportional to the speed of rotation of the rotor.

The output of the induction generator is returned to the input summing network in such phase that it tends to cancel the applied voltage $V_1 \cos \omega_c t$. Ideally, the two voltages would cancel and V_1 and V_2 would be equal. Practically, some difference always exists between V_1 and V_2 but if the gain around the loop is large (that is, if only a very small signal at the output of the summing network is required to produce a large amplitude V_2) the difference between V_1 and V_2 is very small. In such a case the motor speed is closely proportional to the amplitude V_1, and consequently the angular displacement, θ, of the motor shaft is accurately proportional to the integral of V_1 with respect to time.

Although the principle of the integrator is simple the performance of each of its components must be high to secure the desired static and dynamic accuracy. Particular attention must be given to the induction generator since it is the feedback element in the integrator. A generator developed by the Arma Corporation is employed in the computer with characteristics such that the output voltage is proportional to the rotor speed within 0.1 per cent of maximum. With this unit available the principal problem in the development of the integrator was that of obtaining a high-loop gain in order that the accuracy of the integrator would correspond to that of the induction generator. High-loop gain minimizes the effect of variations in the mechanical load on the accuracy of integration. High-loop gain also is important from the standpoint of minimizing the effective time constant associated with the operation of the integrator. By the use of a compensating network as indicated in Figure 13 and by giving careful consideration to the dynamic properties of the elements in the loop, it was possible to reduce the integrator time constant to approximately $1^1/_2$ millisecond.

Considerable difficulty with overload in the amplifier was encountered due to phase shift between the input V_1, to the integrator and the output V_2 of the induction generator. If instead of $V_2 \cos \omega_c t$ the output of the generator is $V_2 \cos (\omega_c t + \phi)$, complete cancellation of the input signal $V_1 \cos \omega_c t$ is not possible, and, due to its high gain, overload may occur in the amplifier even for small values of ψ. As shown in Figure 13, the difficulty is remedied by demodulating the amplifier signal and remodulating to drive the 2-phase motor. Demodulation also permits the use of compensating networks insensitive to changes in frequency of the a-c signal. An important advantage of the integrator lies in the fact that a number of instruments can be driven by the servomotor without impairing the accuracy of integration. In the unit employed in the computer as many as five instruments in addition to the induction generator, are driven by the motor. In most cases these instruments are either resolvers or potentiometers and to increase the flexibility, the mechanical design is such that these instruments can be used interchangeably. The fact that several instruments can be carried on the integrator output permits a sizable reduction in the number of computing components and consequently an important reduction in computing error and time lag.

For example, suppose the quantity $V_1 \int V_2 dt$ is to be computed. The variable V_2 is integrated and one of the potentiometers coupled to the integrator output is excited with a voltage proportional to V_1. The potentiometer output voltage is then the required function. Similarly, a function such as $V_1 \sin \int V_2 dt$ is readily computed by making use of a vector resolver coupled to the output shaft of an integrator. When a number of such operations are required a significant saving in equipment and improvement of performance is effected by use of this type of integrator.

The integrator is shown in Figure 14. In addition to the features already described, the unit includes indicator dials and means for setting initial conditions and starting integration properly at the initiation of the problem solution. The electrical and mechanical portions of the

Figure 20 (above). Angular accelerometer, resolver, and rate gyroscope

integrator together with the input and output amplifiers required by the potentiometers and resolvers driven by the integrator are housed in one rack. Reference has been made already to Figure 6 which shows the general arrangement.

Multiplication

Frequently the computer must carry out the multiplication operation in cases in which either the multiplier or multiplicand occurs as the integral of a variable. In such instances multiplication is performed by the means indicated in the example of the preceding section. That is, a voltage proportional to one of the factors of the desired product is used as the excitation of a potentiometer, the shaft rotation of which is proportional to the factor that occurs as an integral. The output signal of the potentiometer then is the product to be computed.

In other cases, however, neither of the factors appears as a mechanical motion, both occurring in the computer as electrical signals only. In such instances multiplication may be carried out in one of two ways. The first is to transform one of the factors to a mechanical rotation and carry out the multiplication by means of a potentiometer in the manner just described. In this method of multiplication, illustrated by Figure 15, the integrator is made to behave as a position servomechanism and provides a means of transforming an electrical signal into an angular motion. This is achieved by exciting one of the potentiometers coupled to the integrator output with a constant voltage and feeding the signal from the potentiometer, in negative sense, back into the integrator input. Operated in this way, the displacement θ (see Figure 15) of the integrator output is proportional to the electrical signal V_1, which is one of the factors of the desired product. If the voltage applied to another potentiometer is proportional to the second factor, the output of that potentiometer will be the desired product.

However, an important time delay can be introduced by this method of multiplication due to the time required for the integrator motor to rotate the shaft of the potentiometer through the several revolutions often required. A similar type of lag occurs in the operation of the equipment as an integrator, but is not nearly as important since in this case the time delay is proportional to the interval between the moment at which the input signal is applied and that at which the motor reaches its proper rate of rotation. When the unit is employed as a position servomechanism, however, the time delay is proportional to the interval between the application of the input signal and the attainment of the proper angular posi-

Figure 21. Block diagram of flight table servomechanism

tion of the motor. The time delay in the latter case is much larger than that of the former.

If the signal applied to the input of the position servomechanism varies rapidly, this time delay may be so important that this method of multiplication can not be used, and in this case a different method of multiplication is required. The device developed to meet the need is called an electromechanical strain-gauge multiplier and is described elsewhere in the literature. The principle of the device is illustrated by Figure 16. The multiplicand appearing as the electrical signal $V_1 \sin \omega_o t$, is applied to the input of an amplifier controlling an electromechanical transducer similar to a moving coil loudspeaker. The moving element of the transducer is coupled to the moving element (termed the armature) of a strain-gauge bridge. When the armature is displaced from neutral the resistances of the arms of the bridge are altered and a voltage is obtained from the bridge output accurately proportional to the deflection of the armature. The bridge output voltage is fed back to the amplifier input in negative sense with the result that the displacement of the armature becomes proportional to the variable V_1. In addition to the resistance elements of the strain-gauge bridge used in the feed-back path, the resistance elements of a second bridge are attached similarly to the armature, and the mechanical design is such that the unbalance in the second bridge is accurately proportional to that of the feed-back bridge. The excitation of the second bridge, however, is not fixed but is made proportional to the multiplier variable, V_2. Therefore the voltage output of the multiplying bridge is proportional to the product $V_1V_2 \sin \omega_o t$.

It has been possible to achieve an accuracy of 0.1 per cent and an effective time constant of one millisecond by careful design of the electrical and mechanical components of this multiplier. The small time constant is principally attributable to the fact that the maximum excursion of the strain-gauge armature is less than ± 0.002 inch. In practice four strain-gauge bridges are attached to the armature. The unbalance of each bridge is proportional, of course, to the multiplicand V_1. The feed-back bridge is constantly excited but each of the other three bridges can be separately excited, thus making it possible to form three products, V_1V_2, V_1V_3, and V_1V_4. This feature is found useful since in many problems several products must be formed which have a common multiplier. Another possibility is the computation with a single multiplier unit of the square, cube, or fourth power of a variable.

Representation of Arbitrary Functions

Problems are frequently encountered in which a portion of the data is not given analytically but in the form of curves or tables, and the analogue computer must include means for representing such information. While no general analogue means exists for handling this type of data several methods are useful and particular schemes or combinations can be chosen to fit the situation. Certain of the methods of representing arbitrary functions that have been found useful are described briefly.

One of the best methods of representing an arbitrary function is by means of specially wound potentiometers. Potentiometers can be wound to approximate an arbitrary function to within 0.1 per cent provided the function is reasonably smooth. If the function is a rapidly varying one the accuracy of representation is much less. The difficulty with this method is the expense involved in securing a reasonably accurate nonlinear potentiometer. Nevertheless, for several common types of nonlinear function the special potentiometer is one of the most suitable methods of analogue representation. Functions of the type $Y=X^2$, $Y=\tan X$, and $Y=1/X$ are readily handled over a range by this means.

Sometimes the function can be approximated to a sufficient degree of accuracy by a combination of linear and nonlinear functions. One of the simplest methods uses a series of linear functions to represent the desired function. This is illustrated graphically by Figure 17 in which a nonlinear function is approximated by several straight lines. This method of approximation is represented readily in the computer by means of a tapped potentiometer with an adjustable voltage applied at each tap. A schematic of such a device, termed an arbitrary function generator, is illustrated in Figure 18.

The principal advantage of the device is the facility with which it may be set up to represent the usual type of nonlinear function encountered. The accuracy has been found sufficient for most purposes, and can be improved by employing additional taps on the potentiometer and more points on the voltage divider. The fact that the approximation has discontinuous derivatives (since it comprises a series of straight lines) introduces no obvious difficulty since differentiation does not occur in the analogue computer. Difficulties may still be introduced by the fact that a time interval is required to establish in the computer the condition corresponding to a particular linear range. This time interval may or may not be important, depending upon the computer configuration, the magnitude of the change in slope, and the speed at which the problem is solved.

Another method of approximating an arbitrary function is by a combination of linear and nonlinear terms. Taylor's expansion, for example, is a well-known one in which the function $Y=f(X)$ is represented in the neighborhood of point a by the series

$$Y=f(a)+(X-a)f'(a)+\frac{1}{2}(X-a)^2f''(a)$$

where $f(a), f'(a), f''(a)$ and so forth are the value of the function and its derivatives at the point a. The analogue representation of such an expansion is straightforward although complex if many terms in the series are required. The square, cube, and higher order powers of the variable can be represented either by a series of potentiometers wound to represent the various power functions, or by use of multiplier units. Frequently a real saving in equipment and an improvement in accuracy is obtained by departing from a particular type of mathematical expansion. Combinations of trigonometric functions, power functions, and linear terms have been found useful.

The analogue problem becomes much more difficult when the arbitrary function has more than one dependent variable, such as $Z=f(X,Y)$. Series expansions are still useful but even more is accomplished by a judicious cut-and-try procedure involving both experience and intuition.

Flight Table

When the simulator is used to test flight control components, a servo-driven table must be employed to orient those components of the control system that respond to angular motions of the aircraft. The table that simulates the aircraft motion is called the flight table and its design and characteristics are important considerations in the analogue computer. The example of the roll control study discussed earlier (see Figures 2 and 3) required a table with only one axis of rotation since motion of the aircraft about a single axis was being studied. When the complete flight problem is studied the table must have three degrees of freedom in order to simulate

the pitch and yaw as well as the roll motion of the aircraft. The several degrees of freedom of the table, together with the severe requirements on the accuracy and dynamics of its control raised major development problems. These are discussed below.

Mechanical Features

The mechanical structure of the table, which is shown in Figure 19, consists of a platform for carrying the components to be tested, gimbal frames for obtaining the required angular motion, and gearing necessary to move each gimbal. Means are provided for moving the platform about four axes. Motion of the platform about the innermost axis simulates aircraft roll; the gimbal that carries the roll drive mechanism is moved in pitch; and the gimbal carrying the pitch drive mechanism is moved in yaw. Some problems study large motions of the aircraft in pitch and if only three gimbals were provided a condition could be encountered when the pitch gimbal moved through 90 degrees in which the table would have only two degrees of freedom. In order to avoid this situation, called gimbal lock, a fourth gimbal is provided. This gimbal moves in pitch in such a way as to maintain approximately an orthogonal configuration among the three innermost gimbals. Although such situations occur infrequently it is still possible to set up an aircraft maneuver that will produce gimbal lock. When gimbal lock is imminent it is necessary to stop the problem and reorient the gimbals. The problem can then be concluded.

The size of the gimbal frames is determined primarily by the size of the innermost platform, approximately 18 by 24 inches, which in turn is set by the dimensions and weight of the control components that are to be tested. Considerable care must be taken to insure maximum stiffness in the gimbals and their supports since the predominant limitation in the performance of the flight table is imposed by the modes of vibration present in the gimbal structure. The frequencies of these vibration modes are set by the moments of inertia of the gimbals themselves and the load which each carries and the mechanical elastances arising from the bending and twisting of the gimbals, lack of complete rigidity in the gearing, and so forth.

Great care must be taken in the design and construction of the gear train that drives each gimbal in order to minimize backlash, elastance, and friction in the train. Even small amounts of backlash or elastance can cause an oscillation in the flight table when it is servo driven that, although small, may obscure important difficulties in the aircraft control system under study.

Flight Table Instrumentation

The angular position, angular velocity, and angular acceleration of the flight table are measured and used in its control. Angular position measuring elements with the proper characteristics, such as resolvers and potentiometers, already were in existence and further development was unnecessary. However, it was found necessary to carry through a program of development to secure instruments with the desired properties to measure the other two quantities. In both cases it is desirable to measure the angular velocity and acceleration of the platform with respect to axes fixed in the platform in order to minimize problems of vector resolution. The measurement of angular velocity relative to space was obtained by means of a rate gyroscope. The measurement of angular acceleration is made by suspending a mass on frictionless pivots in such a way that it is relatively free to rotate but restrained from moving laterally. If the mass is then restrained in rotation by a spring, the rotation of the mass from its force-free position is proportional to the angular acceleration about the axis of rotation.

Both the angular accelerometer and the rate gyroscope are important links in the servomechanism controlling the flight table and it was necessary therefore that the resolution of both instruments be particularly good. Thus, while an error of about one part in 1000 is considered satisfactory, the resolution of both instruments should be better than this figure by about one order of magnitude. Principally because of the high resolution requirements it was decided to employ strain sensitive resistance gauges as the means of translating the small mechanical motions of each instrument into electrical signals. The primary difficulty with this method of measurement was the relatively large error due to mechanical hysteresis in the strain sensitive wires and their suspension. It was found, however, that the proper technique of suspending the wires and the use of a hard drawn alloy for the wire material permitted the hysteresis error to be reduced to less than 0.1 per cent.

The three principal types of instruments are shown in Figure 20. A total of three angular accelerometers, three rate gyroscopes, 15 resolvers, and one potentiometer is used to instrument the flight table.

Flight Table Servomechanisms

The dynamic characteristics of the servomechanisms driving the flight table gimbals are especially important. It is not only necessary that the time delay of each servo be small but that the servomechanism compensate in part for certain of the time delays of other portions of the control loop. Also important is the magnitude of the power that must be delivered by each servomotor in order to simulate the high angular accelerations and velocities frequently encountered in aircraft motion. It was found that a hydraulic-type servomechanism best fulfilled the various requirements and a block diagram of the system is illustrated in Figure 21. The servomotor is a rotating type, reversible hydraulic motor capable of developing ten horsepower and controlled by a power valve which supplies oil to either line of the motor. The power valve is supplied with oil at 3,000 pounds per square inch from a central source.

Because of the flow forces acting upon the valve and the requirement that it be positioned with a precision of better than 20 microinches, it is controlled by a pilot valve. The pilot valve is moved by an electrical torque motor, so named because of the limited angle through which the rotor turns, which in turn is excited from an amplifier.

Several types of feedback are employed to secure the desired characteristics in the servomechanism. In order to obtain precision of control the position of the power valve is fed back into the controlling amplifier through a compensating network. The angular acceleration of the flight table is measured by means of the angular accelerometer described above and the return of this signal into the controlling amplifier closes the dominant loop of the servomechanism. Because of the fact that an angular acceleration is set up in response to an electrical input signal, the control system is called an acceleration servomechanism. This is in contrast to a positional servomechanism in which the principal feed-back signal is proportional to the *position* of the output. In fact, however, both angular position and velocity signals are measured and fed back in the process of representing the aerodynamic and autopilot control functions of the aircraft.

The dynamic characteristics of the flight table servomechanism, including its load is determined by specifying the response of the acceleration servomechanism.

The effective time delay between the development of the required angular

acceleration and the application of the electrical signal is about two milliseconds.

Solution of a Typical Problem

One of the initial problems studied with the flight simulator was the determination of the stability characteristics of aircraft subjected to large disturbances. Under such conditions the linearity assumptions are not valid and several nonlinear effects must be considered. The complete problem is very complex and requires a lengthy program of machine computation for its solution. Certain specific cases, however, can be considered in a limited time and for the purpose of illustration, a simple problem is discussed here. The physical situation is that of an aircraft stabilized in roll by an elementary control system, but not stabilized in pitch and yaw.

A disturbance, such as might be caused by a gust, is applied simultaneously in roll and pitch, and the transient in each mode of the aircraft motion is to be determined.

The two principal assumptions in the problem are that the forward velocity of the aircraft is constant and that the nonlinearities are limited to certain simple types.

The first assumption is not particularly important for the specific case considered because of the fact that the transient is essentially complete before the aircraft velocity can change appreciably. The second assumption is untenable in many important cases, but was felt to be valid in the situation under study.

The assumption of constant forward velocity reduces the problem to one of five degrees of freedom. Five basic equations may be written, therefore, and under the conditions assumed are the following

$$L_\delta\delta + L_d = IX\frac{dp}{dt} + L_p p \text{ (roll equation)}$$

$$M_d = I_Y\frac{dq}{dt} + (I_Z - I_X)rp + M_q q + M_w w_q \text{ (pitch)}$$

$$0 = I_Z\frac{dr}{dt} + (I_X - I_Y)pq + N_r r + N_v v \text{ (yaw)}$$

$$-W_Z = m\frac{dw}{dt} + mVq - mvp - Z_w w \text{ (normal)}$$

$$W_Y = m\frac{dv}{dt} - mVr + mwp + Y_v v \text{ (lateral)}$$

In the foregoing equations, the symbols have the following definitions:

p, q, r = roll, pitch, and yaw angular velocities measured about the longitudinal, lateral and normal axes of the aircraft, respectively

v, w = rectilinear velocities along the lateral and normal axes

V = forward velocity of the aircraft

I_X, I_Y, I_Z = moments of inertia of the aircraft about the longitudinal, lateral, and normal axes

m = aircraft mass

W_Y, W_Z = components of aircraft weight along the lateral and normal axes, respectively

Z_w = aerodynamic force along the normal axis due to a unit velocity w

Y_v = aerodynamic force along the lateral axis due to a unit velocity v

L_p, L_δ = rolling moments (about the longitudinal axis) due to unit values of p and δ, respectively

M_q, M_w = pitching moments (about the lateral axis) due to unit values of q and w

δ = deflection of the ailerons

L_d, M_d = rolling moment and pitching moment disturbances

The preceding equations are written in terms of a co-ordinate system fixed in the aircraft and the nonlinear terms appear as products of dependent variables. However, the expression for the operation of the roll stabilization system and the explicit expressions for the gravity force require the use of the Euler angles, θ, ϕ and ψ that relate the aircraft axes to axes fixed in space. These equations introduce a number of trigonometric nonlinearities. For the type of control considered in this problem the equation is

$$\delta = k(\sin\theta\cos\phi\sin\psi - \sin\phi\cos\psi)$$

The angles θ, ϕ, and ψ are defined in standard texts on dynamics.

The components of the weight of the aircraft can be written explicitly in terms of the Euler angles in the following equations in which W is the total aircraft weight

$$W_Y = W\cos\theta\sin\phi$$
$$W_Z = W\cos\theta\cos\phi$$

Finally, the angular velocities p, q, and r can be expressed in terms of the Euler angles as follows

$$p = \frac{d\phi}{dt} - \frac{d\psi}{dt}\sin\theta$$

$$q = \frac{d\theta}{dt}\cos\phi + \frac{d\psi}{dt}\sin\phi\cos\theta$$

$$r = \frac{d\psi}{dt}\cos\phi\cos\theta - \frac{d\theta}{dt}\sin\phi$$

A solution of this problem for a particular set of parameters is shown in Figure 22. The machine record was traced to improve reproduction. A very large disturbance was applied in pitch and roll in order to make evident the nonlinear nature of the transient, which is particularly apparent in the record of the yaw transient where the frequency of oscillation is clearly twice the predominant mode occurring in pitch. The delay in the angle of sideslip transient also is interesting.

The angle of attack and angle of sideslip are the inverse sine functions of w/v and v/V respectively. This record was computed by the simulator in about 20 seconds. The speed of operation of the machine thus permits a few hundred of such records to be obtained in a day's time, with sufficient time allowed for parameter changes. The setup time of the machine of course is not included, and this will be more or less lengthy, depending upon the nature of the problem. Ample time must be allowed for this portion of the operation in order to verify carefully the accuracy of solution.

The foregoing example is illustrative of the type of problem encountered in aircraft dynamics. Approximately nine integrators, ten vector resolvers, 20 summing networks, 20 variable-potentiometer multipliers, 30 coefficient potentiometers, and 70 repeater amplifiers were used in the machine setup.

The generalized computer portion of the flight simulator has been in operation since the latter part of 1948 and the flight table has gone through its final tests and is being placed in operation at the present. Approximately 5,000 solutions, not including test solutions, have been computed by the machine since it began operation. The problems were such that each solution would require 100 to 1,000 hours to solve manually with a desk calculator. The operation thus far has been such to establish the merit of the design features and to prove the value of the simulator to aircraft dynamics and related problems.

Excitation System Performance with Motor-Driven Exciters

A. G. MELLOR
ASSOCIATE AIEE

M. TEMOSHOK
ASSOCIATE AIEE

THE performance of the motor-driven exciter as compared with the direct-connected exciter has been presented previously.[1] It has been demonstrated that a co-ordinated excitation system, consisting of an induction motor-driven exciter with added flywheel inertia, can meet satisfactorily the severe excitation requirements resulting from a 3-phase short circuit near the generator bus to which the motor-driven exciter set is connected.

The motor-driven exciter set may be one of a number of station auxiliaries on a bus which derives its power from either the main generator terminals through a transformer, from the external system through a transformer, or from a separate house generator. Under normal operating conditions or under emergency conditions resulting from the failure of an auxiliary power supply, it may be necessary to transfer the station auxiliaries from one bus to another. This study considers the case of the motor-driven exciter set which is transferred from an external power source to the terminals of the main generator. The electrical power input to the exciter motor is zero during the transfer period. The permissible time for this throw-over from one power source to another is determined by the ability of the generator to retain stability during the throw-over period.

A 3-phase fault at or near the terminals of the main generator results in a heavy load on the exciter as the main generator field current increases to several times normal during and following the fault period. The most critical operating condition for the exciter set during the short-circuit fault results when the motor driving the exciter is connected to the main generator terminals. In this case the power input to the exciter motor is zero during the fault period, and the voltage at the motor terminals after the fault is cleared is the recovery voltage of the generator.

The two main purposes of this study are: (1) to determine the length of time that can be taken to transfer the exciter motor from one power source to another and the effect of exciter set and system parameters on this transfer time, and (2) to determine the permissible clearing time of a 3-phase short circuit at the main generator terminals and the effect of exciter set and system parameters on this clearing time.

Scope of Study

The study was performed with the aid of the General Electric differential analyzer. For both the short-circuit and throw-over cases, the following variations of parameters were studied:

1. Effect of excitation methods:

(a). Hand control.
(b). Regulator control.

2. Effect of exciter-set inertia:

(a). $H=1.75$ (no added inertia).
(b). $H=5$.
(c). $H=10$.

3. Effect of main steam turbine generator size:

(a). 20,000 kilovolt-amperes ($H=6.0$, $T_{do}'=6.0$ seconds).

(b). 50,000 kilovolt-amperes ($H=4.5$, $T_{do}'=8.0$ seconds).

(c). 100,000 kilovolt-amperes ($H=3.5$, $T_{do}'=10.0$ seconds).

4. Effect of the size (equivalent reactance) of the system connected to main generator:

(a). Large system with reactance equal to 0.20 per unit (where base kilovolt-amperes equals generator kilovolt-amperes) including transformer.

(b). Small system with reactance equal to 0.40 per unit including transformer.

5. Effect of load power factor, with rated load on main generator:

(a). 0.8 power factor lagging (overexcited).
(b). 1.0 power factor.
(c). 0.8 power factor leading (underexcited).

6. Effect of load on main generator:

(a). Rated load.
(b). 125 per cent rated load.

Assumptions

1. Approximations of effect on exciter voltage of exciter set speed, exciter time constant, and regulator action are given by equation 8A of the Appendix.

2. The motor-driven exciter is unaffected by the other auxiliaries on the station bus.

3. The volt drop of the auxiliary power transformer has been neglected.

4. Regulators

(a). On throw-over, regulator action in holding the main generator terminal voltage constant holds exciter armature voltage constant as exciter speed decreases, until exciter ceiling voltage is reached, after which the exciter voltage is modified by exciter speed and field time constant.

(b). For a short circuit at the main generator terminals, regulator action is complete and instantaneous.

5. The system reactance as seen from the generator terminals remains the same before and after the 3-phase short circuit fault application.

6. Governor action is neglected.

7. The per-unit system of each case is

Conclusions

THROW-OVER CASE (EXCITER MOTOR POWER SOURCE TRANSFER)

1. The maximum permissible throw-over time of a motor-driven exciter set with and without added inertia varies as follows, depending upon the initial operating conditions, the system parameters, and the type of main generator voltage regulator:

(*a*). Without added inertia (H of 1.75)—1.5 seconds to 6 seconds.

(*b*). With added inertia (total H of 5)—4 seconds to at least 10 seconds.

(*c*). With added inertia (total H of 10)—8 seconds to at least 10 seconds.

2. The ability of the excitation system to recover after the throw-over period is secondary to the ability of the system to sustain itself during the throw-over period.

3. (A). Favorable system operation for throw-over is appreciably affected by the following factors:

(*a*). Added exciter-set inertia; decreasing gain results with additional increases in inertia.

(*b*). Increase in the size of the system (lower system reactance) connected to the main generator.

(*c*). Increase in the size of the main generator with the resulting increase in open-circuit field time constant.

(*d*). A unity or leading power factor load on the main generator (generator underexcited), especially for short throw-over times.

(*e*). A high torque characteristic of the induction motor of the exciter set.

(*f*). Regulator action for short throw-over times and underexcited generator loads.

3. (B). Favorable system operation is slightly affected by:

(*a*). Regulator action for overexcited generator loads.

SHORT-CIRCUIT CASE

1. Short-circuit clearing times of one to two cycles less than the critical switching times based on constant generator field flux linkages are possible for all parameters studied.

2. The ability of the excitation system to recover after the short circuit is of equal importance with the ability of the system to sustain itself during the fault.

3. (A). Favorable system operation, during and after the short circuit on the main generator, is appreciably affected by the following factors:

(*a*). Increase in the size of the system connected to the main generator.

(*b*). Decrease in the size of the main generator with the resulting higher inertia factor.

3. (B). Favorable system operation is slightly affected by:

(*a*). Additional exciter inertia.
(*b*). Voltage regulator action.
(*c*). Smaller loads of lagging power factor.

4. Small main generators and generators connected to large systems can withstand longer switching times. Larger generators and generators connected to small systems require shorter switching times but for comparable switching times contribute to more stable system operation.

Discussion of Results

THROW-OVER CASE

The term throw-over implies a transfer of the exciter motor power from one source to another because of an emergency. This power transfer differs from a planned transfer where a synchronizing of the two power sources occurs, and at no time is the exciter motor without power. The minimum time for emergency throw-over is about one-half second and is determined by the ability of the mechanical switch in making the throw-over. This minimum time can impose a heavy, but safe, duty on the motor due to the trapped flux.[3]

If the throw-over is made from the main generator bus to the system or house generator bus, the actual voltage at re-energization due to the voltage drop through the auxiliary power transformer will approach that of the generator voltage used in the study.

If the throw-over is made from the system or house generator bus to the main generator bus, the voltage at the exciter motor terminals will be lower than that used in the study due to the voltage drop in the auxiliary power transformer. Analysis of the results to include the effect of this additional voltage drop indicates a sufficient margin of exciter motor power available for acceleration with no appreciable effect on the ability of the generator to recover and return to normal operation as indicated by conclusion 2 on the throw-over case.

The ultimate criterion in successful throw-over of the motor-driven exciter set from one power source to another is the stability of the main generator with re-

spect to the system. The degree of stability determines the effectiveness of the parameters involved.

For any combination of system parameters, the variables determining the stability of the generator are the generator field flux linkages and the generator angle, as indicated by equation 16. In addition to serving as a criterion of stability, the variation in generator field flux linkages indicates fairly well the performance of other factors in the excitation system. These factors, exciter armature voltage and current, generator terminal voltage, and sometimes the exciter-set speed, vary in approximately the same manner as the generator field flux linkages, as these variables are generally interdependent.

For generators with hand control or normal regulator action and connected to a large system, throw-over times of ten seconds were possible if the motor-driven exciter set has added inertia of an amount resulting in a factor H of 5. The ten seconds time is not a limiting value of throw-over but contains a substantial margin of safety for most cases. It was not thought necessary to study throw-over times beyond ten seconds. The reduction of throw-over time from ten seconds to six seconds occurs with the use of exciter sets with no added inertia and with the generator connected to a small system. Curves *a* and *b* of Figures 1(A) and 1(B) indicate the variation of the generator field flux linkages and generator angle for a 10-second throw-over time. The limit of stability for this particular case results with the machine angle near 120 degrees, and because of reluctance torque the field flux linkages can decrease to about 0.1 per unit, indicating the stability margin available for the 10-second throw-over period.

Study of Figures 1(A) and 1(B) indicates the almost immediate recovery towards normal for both field flux linkages and machine angle after the throw-over was made, indicating very little improvement possible and that the major contribution to system stability would be in sustaining system variables at their normal values as long as possible.

Effect of Exciter Set Inertia

The role played by added inertia to the exciter sets is significant as indicated by Figures 2(A) and 2(B). Instability of the generator resulted with a throw-over time of eight seconds with the use of the exciter set with no added inertia. Flywheel inertia aids in retaining stability but with a decreasing effect with additional increments of inertia. A very appreciable margin in generator stability results by increasing the inertia of the exciter set from the inertia factor H of 1.75 to H of 5. Much less gain in stability margin is experienced by increasing this inertia from an H of 5 to an H of 10, especially on throw-over times up to about five seconds.

Although the slip of the low inertia exciters may become two or three times as great as the slip for the large inertia exciters, the return to normal slip is made in less time as indicated by Figure 2(C).

Effect of System Reactance

Study of equation 16 of generator torque output against generator angle (or power output since the load angle change is small) shows the decrease in power resulting from an increase in system reactance. The change, from the large system with reactance of 0.2 per unit to the small system of 0.4 per unit, causes a decrease in maximum transient generator power of about 50 per cent which decreases the allowable time for throw-over.

Effect of Voltage Regulators

Use of voltage regulators results in little system performance gain. Figures 1(A) and 1(B) illustrate the tendency of regulator action to keep constant initial quantities up to several seconds. This imposes a heavier load on the exciter resulting in a greater loss of speed than for the hand control case where the exciter load decreases immediately at throw-over. For longer throw-over times the system performance with regulator action becomes inferior. Although the exciter voltage has been forced to ceiling by the regulator, the greater slip reduces the armature voltage below that of the hand control case.

Amplidyne regulator results were deduced by analysis of the results obtained with the study with other types of regulators.

Under normal operating conditions of the amplidyne, and assuming that the motor-driven amplidyne is thrown over with the motor-driven exciter, excitation system performance will approximate closely the performance with other types of regulators. Under these conditions the permissible throw-over times of the exciter set are approximately six seconds for the exciter set with no added inertia (H of 1.75) and approximately eight seconds for the exciter set with added inertia (total H of 5).

The minimum throw-over times stated in conclusion 1 are based on the criterion of successful excitation system performance instead of the criterion of generator stability. These minimum times apply to the extreme case in which all external resistance is cut out of the exciter field and the amplidyne is operating bucking. In addition, the motor-driven amplidyne is not thrown over with the exciter set but continues to operate at normal speed. This simulates the opera-

Figure 6(A). Effect of exciter inertia on generator field flux linkages

tion of an amplidyne with very high inertia.

For this extreme case, to determine the absolute lower limit of throw-over times, the voltage at the exciter motor terminals after throw-over was taken as 70 per cent of rated generator voltage, a pessimistic value, instead of the actual voltage at the generator terminals which was considerably higher. Since during the throw-over period the exciter output remains constant at the initial value, the criterion of successful excitation system performance in this case is not the stability of the main generator but the margin of torque available to accelerate the motor-driven exciter after throw-over.

The addition of inertia to the amplidyne maintains the exciter output constant for a longer period, resulting in better voltage regulation but decreasing the margin of torque available for accelerating the exciter set after throw-over.

Effect of Power of the Generator Load

As the load power factor changes from lagging to unity to leading, performance of the system is improved as judged by generator stability. The improved performance is due to two factors as evidenced by a study of Figure 3: more effective regulator action exists because of the higher available incremental field voltage between exciter ceiling voltage and the lower steady-state generator field voltage; and the exciter set is slowed down less due to the smaller exciter load.

Effect of Generator Size

The generator inertia constant tends to decrease as the rating of the generator is increased. Small rating generators tend to have higher inertia factors and lower open-circuit field time constants and large rating generators tend to have lower inertia factors and higher open-circuit field time constants. The larger generators with their longer time constants possess the ability to sustain their field flux linkages as indicated by Figure 4, and therefore their electrical load for a longer period which tends toward greater stability.

Short-Circuit Case

There are two criteria of system performance during and after a 3-phase short circuit. One criterion of performance is the maximum time for clearing a 3-phase short circuit. A second criterion is system performance during and after the short circuit for various clearing times. For most cases studied a switching time of one cycle less than the critical switching time, based on constant generator field flux linkages, resulted in stable operation. For the worst cases a switching time of $2^1/_2$ cycles less than this critical switching time was necessary. But, as can be seen in Figure 5(A), the flux linkages decay appreciably during the fault period. The

actual critical switching time can be calculated closely knowing the changing value of field flux linkages. Although switching times in the study approximate the actual value of critical switching time, no attempt was made to switch at this exact value, but at some value approaching it. Therefore, most or all switching times studied are slightly low but practically identical to the actual critical switching times. The average switching times of the cases studied were about 0.25 second (15 cycles).

For a short-circuit fault, the generator field flux linkages do not decay as much as for the throw-over case, and the generator can advance to about 160 degrees in most cases and still remain stable. The severe transients encountered during the fault make it as important for the excitation system to sustain itself during the fault as to recover after the fault is cleared. Figures 5(A) and 5(B) illustrate the almost equal increments of change in the generator field flux linkages and load angle during the fault and during the recovery period.

Effect of Exciter-Set Inertia

Study of Figures 6(A) and 6(B) demonstrates that practically no difference exists with exciters with inertia factors, H of 5 and 10 for the important variables, generator field flux linkages and generator load angle. The exciter-set slip, from time of short circuit to return to normal, varies inversely as the exciter-set inertia, as illustrated by Figure 6(C).

Effect of System Connected to the Main Generator

As for the throw-over case where the small system with its high reactance as seen from the generator terminals reduced the possible throw-over time, so for the short-circuit case the small system reduces the possible switching time. Approximately a 50 per cent longer switching time is possible for the large system than the small. If switching times for both cases are equal to or less than the critical switching time of the small system case, the system performance is practically the same.

Effect of Regulator Action

Regulator action has practically no effect on stability performance. Quicker system recovery is possible with regulator action, but this effect is moderate.

Effect of Generator Size

The size of the generator has a pronounced effect on all the variables studied. Since critical switching time varies as the inertia constant of the alternator, small machines having larger inertia constants would have the longest switching times. If switching times were equal to or less than the critical switching times of the largest generators, the latter have the better performance because of their longer field time constants, resulting in less change from normal for all variables. Figure 7, indicating the change in generator field flux linkages, is representative of changes in the other variables.

Effect of Main Generator Load and Power Factor

The effect of additional electrical load on the generator is to shorten the critical switching time. The actual system performance of generators carrying rated load and 125 per cent rated load is practically identical for the same switching times, for which both are stable.

Load power factor influences regulator action and exciter-set load. The excitation requirement for a leading power factor load is lower than for a lagging power factor load, and hence the exciter slows down much less during the short-circuit period. The exciter is capable of maintaining a higher excitation level because of its higher speed, and regulator action is more effective due to the greater increment between exciter ceiling and operating voltages. This sustained exciter output in turn tends to keep all other variables from changing.

Summary

Two criteria of satisfactory system performance are the ability of the main generator to retain stability and the ability of the exciter set to recover after a disturbance. Normal emergency throw-over times are generally between one and two seconds. This study indicates that for these throw-over times a very substantial margin in system performance exists, with the use of a special design of motor-driven exciter set with an inertia constant H of 5 and a maximum torque of about 325 per cent rated. This exciter set does not require a shorter throw-over time than any other essential station auxiliary. The high torque characteristic of the induction motor enables satisfactory system performance to be obtained with voltage at the motor terminals as low as 70 per cent of normal both on steady state and on re-energization after throw-over.

With this exciter, for a 3-phase short-circuit fault at or near the generator terminals, the maximum permissible switching time closely approaches the actual critical switching times which vary between approximately 11 and 20 cycles for the conditions studied. Practical switching times are generally below ten cycles. Additional special design considerations of the exciter set as presented in reference 1 further improve performance for the short-circuit fault operation.

Appendix

The system diagram is shown in Figure 8, and the vector diagram in Figure 9. The noureciprocal unit system of Park[3] was used for the generator equations.
